Abstract. The major target tissues for Epstein-Barr virus (EBV) infection are B lymphocytes and epithelial cells of the oropharyngeal zone. The product of the EBV BZLF1 early gene, EB1, a member of the basic leucine-zipper family of transcription factors, interacts with both viral and cellular promoters and transcription factors, modulating the reactivation of latent EBV infection. Here, we characterize a novel cellular protein interacting with the basic domains of EB1 and c-Jun, and competing of their binding to the AP1 consensus site. The transcript is present in a wide variety of human adult, fetal, and tumor tissues, and the protein is detected in the nuclei throughout the human epidermis and as either grainy or punctuate nuclear staining in the cultured keratinocytes. The overexpression of tagged cDNA constructs in keratinocytes revealed that the NH2 terminus is essential for the nuclear localization, while the central domain is responsible for the interaction with EB1 and for the phenotype of transfected keratinocytes similar to terminal differentiation. The gene was identified in tail-to-tail orientation with the periplakin gene (PPL) in human chromosome 16p13.3 and in a syntenic region in mouse chromosome 16. We designated this novel ubiquitously expressed nuclear protein as ubinuclein and the corresponding gene as UBN1.

Key words: Epstein-Barr virus • epidermis • protein–protein interaction • keratinocyte differentiation • chromosome 16

Introduction

Epstein-Barr virus (EBV)1 is a human herpes virus that persists in latency for the lifetime of the infected host. Transmission by oral contact results in infection of the oral and/or nasopharyngeal epithelium, and subsequent infection of B lymphocytes in the adjacent lymphoid tissue en-
entiating cells. The undifferentiated cells of the basal cell layer are responsible for the cell-basement membrane attachment through the adhesion complexes, called hemidesmosomes. When the cells lose their contact to the basement membrane, they start to travel towards the upper layers of the epithelium, changing their appearance as typical for the terminally differentiated cells. The cell-cell adhesion mediated through desmosomes and adhesion junctions plays an important role in the integrity of epithelium. The terminally differentiated keratinocytes flatten and develop the cornified envelope, the structure around the cell wall, which has a significant impact on the barrier function of epithelia. The pattern of genes expressed changes along the differentiation stage of the cells. Specific transcription factors and transcriptional regulators contribute to the differentiation of epithelial cells (Fuchs, 1995; Eckert et al., 1997).

Many of the known transcriptional regulators have been identified through DNA–protein or protein–protein interactions. The EBV transcription factor EB1 (also called ZEBRA, Z, or Zta) is a member of the basic leucine-zipper family (Farrell et al., 1989; Chang et al., 1990; Lieberman and Berk, 1990). The Z1P transcription factors, including Jun, Fos, ATF/CREB, and C/EBP family of proteins, form homo- and heterodimers through a coiled-coil domain, also called a leucine zipper, and bind DNA through a region rich in basic amino acids, located adjacent to the dimerization domain. The protein complexes known as A P1 and A P2 have an important function in the regulation of gene expression in the epithelial cells (Fuchs, 1995; Eckert et al., 1997). EB1 is a sequence-specific DNA-binding protein that activates transcription from specific EBV promoters, as well as the promoters of some cellular genes, thereby initiating the viral lytic cascade. The first 167 NH2-terminal residues of EB1 are involved in the transcriptional activation, while the remaining 78 residues form the DNA binding and dimerization domains. The retinoic acid receptors, RARα and RXRα (Sista et al., 1995), as well as p53 and p65 (Gutsch et al., 1994; Zhang et al., 1995), as well as p53 and p65 (Gutsch et al., 1994; Zhang et al., 1995), have been shown to interact with EB1, suggesting that the viral protein EB1 may influence cellular regulatory pathways. The protein–protein interactions between the basic domain of EB1 and the key cell cycle control proteins are indeed involved in cell cycle arrest (Rodriguez et al., 1999). The molecular functions by which transcriptional regulators modulate polymerase II–mediated gene expression are initiated by the recruitment of components of the transcriptional preinitiation complex. The components are thought to be involved either individually or as holozymy complexes with coactivators and corepressors, and as complexes affecting chromatin organization (for references see Workman and Kingston, 1998; Berger, 1999; Berk, 1999; Hampsey and Rineberg, 1999). A cation of transcription by EB1 has been shown to occur in vitro by direct contact of TFII D (Lieberman et al., 1997). A direct interaction between the basic domain of EB1 and TBP has also been documented in vitro (Michel et al., 1993b).

Two independent approaches reported in this study led to the biological characterization of a novel nuclear protein in human cells. Initially, partial cDNA was isolated through expression cloning while screening for cellular factors interacting with EBV EB1 protein. Independently, during characterization of the periplakin (PPL) locus (Aho et al., 1999), another previously unrecognized gene was identified. Further studies revealed that this gene is ubiquitously expressed and encodes a nuclear protein, capable for interacting with viral and cellular transcription factors. Consequently, we have designated this novel gene as ubinuclein (UBN1). Here, we detail cloning and chromosomal localization of the UBN1 gene, its tissue-wide expression, and structural and functional characteristics of the encoded protein, ubinuclein.

### Materials and Methods

#### cDNA Cloning

A 1-kb partial cDNA clone was isolated through screening of the HeLa cell cDNA library in Xgt11. A 40 × 106 phages were screened with biotinylated EB1, essentially as described by MacGregor et al. (1990). EB1 was produced in E. coli and labeled by direct contact of TFIID (Lieberman et al., 1994), as well as p53 and p65 (Gutsch et al., 1994; Zhang et al., 1995), for references see Workman and Kingston, 1998; Workman and Kingston, 1995; Eckert et al., 1997). The cloning and sequencing of the human periplakin gene (PPL) was described previously (Aho et al., 1999). During characterization of PPL, the P1 clone G5#4060 was used as a template for direct DNA sequencing, which revealed the 3′-end of UBN1. Genomic clones containing the UBN1 gene were obtained by screening a human placental lambda FIX II library (Stratagene) with a 284-bp PCR product from the 5′-end of cDNA, produced with primers 5′-A GA TGA CAC TTA TGA CAA-3′ and 3′-GGT CAA GGA TCT AGG ATA CA-3′ (Sista et al., 1995), as well as p53 and p65 (Gutsch et al., 1994; Zhang et al., 1995), have been shown to interact with EB1, suggesting that the viral protein EB1 may influence cellular regulatory pathways. The protein–protein interactions between the basic domain of EB1 and the key cell cycle control proteins are indeed involved in cell cycle arrest (R. Rodriguez et al., 1999). The molecular functions by which transcriptional regulators modulate polymerase II–mediated gene expression are initiated by the recruitment of components of the transcriptional preinitiation complex. The components are thought to be involved either individually or as holozymy complexes with coactivators and corepressors, and as complexes affecting chromatin organization (for references see Workman and Kingston, 1998; Berger, 1999; Berk, 1999; Hampsey and Rineberg, 1999). A cation of transcription by EB1 has been shown to occur in vitro by direct contact of TFII D (Lieberman et al., 1997). A direct interaction between the basic domain of EB1 and TBP has also been documented in vitro (Michel et al., 1993b).

#### Genomic Cloning

The cloning and sequencing of the human periplakin gene (PPL) was described previously (Aho et al., 1999). During characterization of PPL, the P1 clone G5#4060 was used as a template for direct DNA sequencing, which revealed the 3′-end of UBN1. Genomic clones containing the UBN1 gene were obtained by screening a human placental lambda FIX II library (Stratagene) with a 284-bp PCR product from the 5′-end of cDNA, produced with primers 5′-A GA TGA CAC TTA TGA CAA-3′ and 3′-GGT CAA GGA TCT AGG ATA CA-3′, in combination with an exon 2-specific reverse primer 5′-A GC TCT GGG TAG AAG-3′.

#### Northern Analysis

Human cancer cell line multiple tissue Northern blot was obtained from Clontech. The 284-bp PCR product described above was 7P-labeled and used as a probe, and the RNA blot was hybridized according to the manufacturer’s instructions.

#### PCR Analysis of Multiple Tissue cDNA Panels

Human multiple tissue cDNA panels (human MTC panels I and II, human fetal MTC panel, and human tumor MTC panel) were obtained from Clontech and used as templates for PCR analysis. The ubiquinuclein exons 1A–specific primer 5′-GGG ACC GGC GGG AGT AGG AC-3′, exon 1B–specific primer 5′-G GT CAA GGA TCT AAG ATA CA-3′, and exon 2–specific primer 5′-A GA GGC CAT GCA GTG ACA C-3′, in combination with an exon 2–specific reverse primer 5′-A GC TCT GGG TAG AAG-3′.

---

The Journal of Cell Biology, Volume 148, 2000 1166
A C T 3', produced PCR fragments of 304, 483, and 243 bp, respectively. PCR conditions were: 2 min at 94°C, followed by 38 cycles of 94°C for 20 s, 58°C for 30 s, and 72°C for 1 min. PCR was conducted using Taq DNA Polymerase and the Q-solution provided with the kit (Qiagen). G3PDH-primers, provided by Clontech with each MTC panel, were used as a control, and the PCR was performed for 30 s at 94°C, followed by 26 cycles of 94°C for 20 s and 68°C for 2 min. The PCR-products were separated on 1.5% agarose-TBE gels.

In Vitro Interaction Assays

Glutathione S-transferase (GST)-ZAP5 fusion protein was expressed in E. coli, and purified according to the instructions (Pharmacia Biotech). The GST-ZAP5 bound to glutathione agarose was incubated in vitro-translated (Promega) 35S-labeled EB1, Z (Girot et al., 1991; Mikaelian et al., 1993a) and C/EBP (Landschulz et al., 1988), essentially as described by M an et al. (1993). Bound proteins were loaded onto a 10% SDS-PAGE and visualized by autoradiography.

Electrophoretic Mobility Shift Assay (EMSA)

EMSAs were performed by incubating 4 × 10⁶ cpm of 5' 32P-labeled double-stranded oligonucleotide probe, 5'-CTG AGC GGA AGC ACT GAC TCA TGA AGG TGC 3'- (AP1 consensus site underlined) with 2 μl of in vitro-translated proteins for 30 min at room temperature in 20 mM HEPES, pH 7.9, 100 mM KCl, 1 mM MgCl₂, 0.5 mM DTT, 10% glycerol, and 1 μg of poly(dI-dC) in a final volume of 20 μl. After incubation, the mixture was loaded onto a 4.5% (wt/vol) polyacrylamide gel (29 to 1 cross-linked), separated onto nitrocellulose membrane, and detected by the affinity-purified rabbit serum. The secondary antibody, conjugated with HRP, was detected with Renaissance Western blot chemiluminescence reagent (New England Nuclear Life Science Products).

Expression Constructs

The CMV-based expression vectors for EB1 (pCMV-EB1) and EB1-GCN4 (pCMV-EB1-GCN4) have been described elsewhere (Segoffin et al., 1996). The Flag-tagged ubinuclein constructs were prepared using the expression vector pRc/CMV (Invitrogen). The EB1 constructs with point mutations in the basic domain or the basic domain replaced by the c-jun basic domain (Z) have also been described elsewhere (Mikaelian et al., 1993a).

Cell Cultures and Transfection Studies

Primary foreskin keratinocytes and HaCaT keratinocytes were cultured in the KGM medium containing 0.15 mM Ca²⁺ (Clonetec). The transfections were executed using the FuGENE 6 transfection reagent according to the instructions provided by the manufacturer (Boehringer Mannheim Corp.). Cells were harvested 9 or 21 h after transfection, washed three times with PBS, fixed for 5 min in absolute methanol at –20°C, and processed for indirect immunofluorescence (IF).

Immunological Analysis of Ubinuclein Protein

Rabbit polyclonal antibody was raised against the bacterially expressed ZAP5-GST fusion protein. Rabbit serum was passed several times through a glutathione Sepharose 4B GST column to bind the anti-GST antibodies. The flow-through was loaded on the Glutathione Sepharose 4B GST-ZAP5 column to bind the antibodies, which were eluted at low pH. A Z125 mAb against EB1 has been described (Mikaelian et al., 1993a). Mouse anti-Flag-tag antibody M2 was purchased from Stratagene, and mouse monoclonal antiactin antibody from Boehringer Mannheim Corp.

For the Western blot, cells were harvested 24 h after transfection, washed three times with PBS, and dissolved directly into SDS-gel loading buffer. Proteins were separated by SDS-PAGE on 10% acrylamide, transferred onto nitrocellulose membrane, and detected by the affinity-purified ZAP5 antibody. The secondary antibody, conjugated with HRP, was detected with Renaissance Western blot chemiluminescence reagent (New England Nuclear Life Science Products).

A section of human newborn foreskin, embedded and frozen in the OCT compound, was cut into 7-μm cryosections, which were air-dried. Slides with tissue sections or with cultured keratinocytes were rinsed with PBS, fixed in methanol at –20°C for 5 min, cells were permeabilized with 0.1% Triton X-100 in PBS for 5 min at room temperature, washed three times with PBS, and blocked with 1% BSA in PBS for 1 h at room temperature. The primary antibodies were applied on the samples overnight at 4°C. A tetramethylized wash with PBS, samples were incubated for 1 h at room temperature with the species-specific secondary antibody conjugated to Texas red or Fluorescein (Jackson Laboratories), washed four times with PBS, and mounted with Anti-Fade (Molecular Probes). Sections and slides were studied under fluorescent microscope (Axioskop; Carl Zeiss, Inc.), images were stored with ImagePro Plus 4.0 imaging software (Media Cybernetics) and processed with Photoshop 5.0 (Adobe Systems Inc.) and Canvas 5 (Deneba Software).

Results

Molecular Cloning of the Human Ubinuclein Gene and cDNA

We recently reported characterization of periplakin cDNA and the corresponding gene (PPL) (Aho et al., 1998, 1999). DNA sequences downstream from the periplakin polyadenylation signal (AATAAA) obtained from the genomic P1 clone GS14060 (GenBank/EMBL/DDBJ A F041004 and A F108459) were subjected to the homology search by the BLAST algorithm (Altschul et al., 1997), which revealed an unexpected match with a large number of cDNA clones in the GenBank/EMBL/DDBJ EST database. Furthermore, sequencing of the opposite end of the P1 clone (GenBank/EMBL/DDBJ A F108458; Fig. 1 A) revealed a 146-bp sequence with complete match within the VT4 cDNA (GenBank/EMBL/DDBJ U19346), which has been isolated by screening a HeLa cell expression library for proteins that bind to a negative regulatory element (NRE1) in the long terminal repeat (LTR) of human immunodeficiency virus type 1 (HIV 1; Tesmer et al., 1993; M. Bina, Purdue University, personal communication).

In an independent approach, human HeLa cell ZGT11 cDNA expression library was screened with the in vitro-translated and biotinylated EBV transcription factor EB1. A mong the positive clones, one contained a 1-kb EcoRI insert, identical to the VT4 cDNA, with an open reading frame allowing the translation of the putative interacting fusion protein, but did not contain either translation initiation or termination codons. The 1-kb EcoRI fragment was used as a DNA probe in a second screening of the ZGT11 library and a longer cDNA clone, ZAP5, was isolated. Rapid amplification of the cDNA library DNA with a pair of vector specific and cDNA-specific primers resulted in the extension of the 5'-end by 1.5 kb of cDNA sequences (Fig. 2). The 2.3-kb 3'-untranslated region (UTR), sequenced from a genomic P1 clone, was verified by DNA sequencing of the PCR-products generated using specific primers and a human keratinocyte cDNA library as a template. A single polyadenylation signal, AATAAA, was detected 2.3 kb downstream from the translation termination codon TGA. Human EST sequences cover almost 80% of the ubinuclein cDNA, including the 5'-end and the entire 3'-UTR (BLAST search of the dbEST 12/22/99).

Genomic Organization of UBN1

Sequencing of the P1 clone, combined with the isolation and sequencing of overlapping genomic λ-clones, revealed that the human ubinuclein gene spans ~70 kb of genomic DNA on the short arm of chromosome 16 (Fig. 1 A). The full-length ubinuclein cDNA sequence identified 18 distinct exons in the genomic DNA. Two alternative 5'-exons, preceded by putative promoter sequences, were identified
The distance between the corresponding polyadenylation signals (AATAAA and TTTATT, underlined) is 194 bp. The orientation. The distance between the two polyadenylation signals in mouse intergenic regions did not show sequence homology, the distance between the two polyadenylation signals in mouse orientation, the distance between the polyadenylation signals of the two human transcripts being 194 bp (GenBank/EMBL/DDJB A F041004; Fig. 1 B). Although UBN1 and PPL genes together extend >150 kb of genomic sequences, the 23-kb central region of the P1 clone G S14060 contains 19 exons, which occupy 40% of the genomic DNA encoding 76% of the two cDNA sequences. Interestingly, a VT4 protein pseudogene was recently identified in clone 551E13 on human chromosome Xp11.2-11.3 (GenBank/EMBL/DDJB A L022163).

DNA sequencing of a mouse genomic clone downstream from the 3'-end of the periplakin gene, Ppl (GenBank/EMBL/DDJB A F116523), revealed high homology to the corresponding region in the human genomic clone. The BLAST search of the EST database with mouse genomic sequence identified a set of mouse cDNA clones, highly homologous to the human ubinuclein 3'-sequences, confirming a tail-to-tail arrangement for Ppl and Ubn1, similar to the human genes. Although human and mouse intergenic regions did not show sequence homology, the distance between the two polyadenylation signals in mouse was similar to that in human, 197 bp (Fig. 1 C).

Predicted Ubinuclein Amino Acid Sequence

The human ubinuclein open reading frame starts in exon 2 from an ATG codon which is preceded by an in-frame translation stop codon, TAA, only six triplets upstream (Fig. 2). The flanking sequence GtaGCC A T Gt surrounding the start codon is in agreement with the Kozak consensus sequence GCC(A/G)CCA T G (Kozak, 1991, 1996).

The open reading frame within the full-length UBN1 cDNA encodes a polypeptide, 1,134 amino acids long, with a calculated molecular mass of 121,529 D (Fig. 2). The entire protein is basic, pI 9.34, and rich in serine and lysine, 12.79% and 10.58%, respectively. The secondary structure prediction suggests that the NH2-terminal half of the protein, which is mainly composed of charged amino acids, forms several α helices, while the COOH-terminal half, with polar/nonpolar amino acids dominating, is flexible with high abundance of β-turns. Five acidic regions were identified within the NH2-terminal half of ubinuclein: amino acids 31-56 with pl 5.31; amino acids 122-180 with pl 3.52; amino acids 281-390 with pl 3.89; amino acids 450-503 with pl 5.01; and amino acids 621-720 with pl 4.71 (Figs. 2 and 6). The alternating acidic and basic domains have a potential to form secondary structures, which are known to interact with DNA. Indeed, the partial VT4 cDNA clone (GenBank/EMBL/DDJB U19346), encoding ubinuclein amino acids 346-693, was cloned through DNA–protein interaction (see above; Tesmer et al., 1993). Several clusters of basic amino acids, altogether 11, which fulfill the requirements of either SV40-type (Kaderon et al., 1984) or nucleolin-type (Dingwall et al., 1988) nuclear localization sequences, were identified. Especially, the amino acids 180-262 segment contains five repeats of possible phosphorylation sites, including consensus sequences for protein kinase C, casein kinase II, cAMP phosphokinase, and tyrosine phosphorylation. A domain rich in serines (DRS) was identified within the COOH-terminal region, amino acids 866-932, and a ATP/GTP binding site homologous to Walker A motif (Walker et al., 1982) was identified at the COOH terminus, amino acids 1119-1127.

Interspecies Homology of the Ubinuclein Transcript

The homology between the human ubinuclein 5'-end with 557 bp of mouse EST sequences was 91%. In addition to human and mouse ESTs, a cDNA clone from Sus scrofa (emb/F23010/SSC18E02) showed 86% identity with the 5'-end of human sequence. A ligament of the human 3'-UTR
Figure 2. Nucleotide sequence of the cDNA encoding ubinuclein and the predicted amino acid sequence. Numbering of the cDNA sequence begins from the first nucleotide of the putative translation initiation codon, ATG, which is preceded by an in-frame stop codon, TAA, only six triplets upstream (underlined). Two alternative 5' 3'-ends probably due to the multiple promoter usage, denoted Exon 1A and Exon 1B, were discovered. Five nucleolin-type acidic regions are highlighted by shading. Repeats of basic amino acids with homology to nuclear localization signals are underlined by dashed lines and numbered (1–11). The serine-rich region is denoted with dotted underlining and the ATP/GTP consensus binding sequence (amino acids 1119–1127) is underlined. The open reading frame encoding a polypeptide of 1134 amino acid residues terminates in a stop codon (indicated by an asterisk), which is followed by a consensus polyadenylation signal (AATAAA, underlined) at the end of the 2280-bp 3'-UTR.
sequences with the two contigs of mouse ESTs (696 and 907 bp) indicated 75% identity overall. An EST clone of Rattus norvegicus (GenBank/EMBL/DDBJ AI112799; Bonaldo et al., 1996) showed 96% identity to the 3'-UTR of the mouse ubinuclein. Collectively, the nucleotide sequences around the ATG codon and the 3'-UTR sequences, especially those immediately surrounding the AATAAA consensus signal, showed considerable homology between human, mouse, rat, and pig, significantly higher than would be expected from the 3'-UTR extending >2 kb beyond the translation termination codon.

**Ubinuclein Transcript is Constitutively Expressed in Fetal and Adult Tissues**

Human multiple tissue cDNA panels were used as PCR templates to study the ubinuclein expression in both adult and fetal tissues. With the exon 2-specific primers, the ubinuclein transcript was detected in all of the normal tissues, as well as in a set of human tumor tissues (Figs. 3 and 4 A). Ubinuclein cDNA cloning revealed two alternative 5'-ends, which were identified in the genomic clone as two alternative exons, 1A and 1B, encoding two alternative 5'-UTRs (Fig. 2). The primers specific for exon 1A-exon 2 produced a PCR product from all the templates used, while exon 1B-exon 2-specific primers produced a PCR product from tumor cells, fetal tissues, and a limited number of adult tissues (Figs. 3 and 4 A).

The hybridization of human cancer cell line multiple tissue Northern blot revealed that the transcript was present in various cancer cell lines (Fig. 4 B). The 7-kb transcript detected on the Northern blot is in agreement with the 6.3-7.0 kb of cloned cDNA sequences. On the Northern blot, only a single band was detected, suggesting that one of the alternatively used promoters was expressed on a relatively low level. The BLAST search identified human ESTs originating from a wide variety of tissues and cells, including heart, retina, gall bladder, liver, testis, and ovary; fetal heart, liver, and spleen; an ovarian tumor, an en-

![Figure 3](image1.png)  
**Figure 3.** Expression of ubinuclein transcripts in human adult and fetal tissues. The multiple tissue cDNA panels I and II (first two panels), and human fetal panel (last panel) were used as PCR templates. PCR primers specific for exon 1A-exon 2, exon 1B-exon 2, and exon 2 of ubinuclein, and for G3PDH as an internal standard, were used. CDNA's were derived from polyA + RNA isolated from tissues indicated on the top and the quantity was normalized against the transcripts of several housekeeping genes. In most tissues, transcripts with exon 1A-exon 2-specific primers were detected at the equal level, whereas a transcript containing exon 1B was less abundant.

![Figure 4](image2.png)  
**Figure 4.** Expression of ubinuclein transcript in human tumor tissues. A. Tumor tissue cDNA panel was used as a PCR template as described in Fig. 3. Lane 1, Molecular weight marker, 100-bp ladder; lane 2, negative control; lane 3, colon adenocarcinoma (GI-112); lane 4, colon adenocarcinoma (CX-1); lane 5, pancreatic adenocarcinoma (GI-103); lane 6, prostatic adenocarcinoma (PC-3); lane 7, lung carcinoma (GI-117); lane 8, lung carcinoma (TX-1); lane 9, breast carcinoma (GI-101); lane 10, ovarian carcinoma (GI-102). B. Northern blot analysis of human mRNA. Hybridization of the human cancer cell line multiple tissue Northern blot with the ubinuclein-specific probe revealed a transcript of 7 kb. G3PDH-specific probe was used as a control. Lane 1, Promyelocytic leukemia HL-60; lane 2, HeLa cells S3; lane 3, chronic myelogenous leukemia k-562; lane 4, lymphoblastic leukemia MOLT-4; lane 5, colorectal adenocarcinoma SW40; lane 6, lung carcinoma A 549; lane 7, melanoma G 361.
dometrial tumor, and T cell lymphoma; as well as Jurkat T cells and activated T cells. Furthermore, mouse EST clones derived from various adult tissues, as well as from unfertilized egg, 2-cell stage mouse embryo and 8.5-, 13.5- and 19.5-d mouse embryos were identified. One of the pig 3'-UTR clones in the EST database has been identified by differential hybridization of a granulosa cell cDNA library (GenBank/EMBL/DDBJ no. X91689; Tosser-Klopp et al., 1997).

**Demonstration of the Nuclear Localization of Ubinuclein Protein**

Because PCR analysis revealed that ubinuclein is a relatively common transcript in human keratinocyte cDNA library (data not shown), we applied IIF analysis to study the expression and localization of ubinuclein protein in human skin and keratinocytes in culture. Frozen sections of human newborn foreskin revealed intense nuclear signal with ZAP5 antibody throughout the epidermis (Fig. 5 A). Human foreskin keratinocytes in culture showed staining both in fine granular nuclear pattern, as well as in distinct nuclear dots (Fig. 5 B).

**Overexpression of Ubinuclein cDNA in Cultured Keratinocytes Results in Morphological Changes Resembling Terminal Differentiation**

Overexpression of the full-length Ubi-F, but not Ubi-Z or Ubi-N, resulted, after the initial nuclear localization, in the spreading of the transfected cells and redistribution of the Flag-tagged Ubi-F into the cytoplasm. A circular pattern of dots radiating from the nucleus was often distinguished from the uniform cytoplasmic staining (Fig. 7 A, Ubi-F panel on right). Remains of cells, seen on the top of the basal cell layer and strongly staining with ZAP5 and M2 antibodies, suggested disintegration and shedding of the transfected cells, resembling the terminal differentiation of primary keratinocytes in culture (Fig. 7 B).

On the Western blot, the ZAP5 antibody detected a 150-kD band from the keratinocyte extract (Fig. 8). From the cell cultures expressing full-length construct Ubi-F, a single band of 150 KD was detected, while the polypeptide encoded by Ubi-Z/ZAP5 construct appeared as a slightly faster migrating band, and Ubi-N polypeptide was seen as a 50-kD band. In latter cases, the endogenous 150-kD band was also detected (Fig. 8).

**EB1 Expression Interferes with Endogenous Expression of Ubinuclein**

As ubinuclein was initially identified through interaction
Figure 7. Expression of transiently transfected ubinuclein constructs Ubi-F, Ubi-N, and Ubi-Z/ZAP5, as well as EB1 in primary foreskin keratinocytes. The cultures were stained either with ZAP5 antibody detecting both endogenous and transfected ubinuclein, with M2 antibody recognizing the Flag-tag, or with DAPI for DNA to visualize the nuclei. A, NH2-terminal 345 amino acids contain sufficient information for the nuclear localization of ubinuclein. Cells were prepared for IIF 9 h after transfection of the expression constructs denoted on the top of each panel. Flag-tag signal (M2 ab) colocalized with the signal obtained with ZAP5 antibody. The endog-
with EB1 protein, we overexpressed EB1 in primary keratinocytes by transiently transfecting cells with an expression construct under the control of CMV promoter. IIF revealed that, in the cells where EB1 was overexpressed, the endogenous ubinuclein signal was either undetectable or weaker than in untransfected neighboring cells (Fig. 7 C). Cotransfection and subsequent overexpression of the full-length ubinuclein, Ubi-F, together with EB1, resulted in a similar appearance of cells as detected with the Ubi-F construct (Fig. 7 D). The colocalization of ubinuclein and EB1 was first limited to the nucleus. However, both proteins were also detected in the cytoplasm of the cells that appeared flat and were spread out on the top of the basal cell layer (Fig. 7 D), whereas the cells expressing only EB1 showed normal cellular morphology and exclusively nuclear staining with EB1 antibody (Fig. 7 C). The distinct cytoplasmic colocalization in a punctate pattern suggests that ubinuclein and EB1 are capable of interacting in vivo.

Ubinuclein Interacts In Vitro with the Basic Domain of both Cellular and Viral bZIP Transcription Factors

Because a partial ubinuclein cDNA clone was originally isolated through the interaction with EB1, we wanted to identify the domain in EB1 responsible for the interaction. A polypeptide, encoded by Ubi-Z/ZAP5 cDNA (Fig. 6), was expressed as a GST fusion protein in E. coli and immobilized to glutathione agarose particles. A series of in vitro-translated EB1 polypeptides with deletions within each domain and point mutations within the basic domain (Fig. 9 A) was tested for the affinity to the Ubi-Z/ZAP5 polypeptide. We observed that the interaction between

**Figure 9.** Ubinuclein binds to the basic domain of EB1. A, The EB1 protein is composed of the activation domain (amino acids 1–175), DNA-binding domain (DB; amino acids 178–195), and the dimerization domain (Di; amino acids 196–233). A set of deletion constructs and amino acid substitutions were prepared, as indicated in the bottom of A. B, The interaction between the in vitro-translated EB1 constructs (a) and Ubi-Z/ZAP5 (b) was impaired by the deletion of EB1 DNA-binding domain (lane 4), mutations in the EB1 DNA-binding domain (lanes 7 and 8), or the deletion of the dimerization domain (lane 5). Ubi-Z/ZAP5–GST fusion protein bound to the GT-agarose was used as the affinity matrix. Asterisk marks the low molecular weight protein, Z42-199 (a, lane 4).

Ubi-Z/ZAP5 and EB1 was impaired when the EB1 basic domain (Fig. 9 B, lane 4) or the EB1 dimerization domain (Fig. 9 B, lane 5) was deleted. To pinpoint the amino acids within the EB1 basic domain critical for the binding to Ubi-Z/ZAP5, we assessed the ability of three EB1 constructs carrying point mutations, Z306, Z310, and Z311, to

---

enous signal was detectable with ZAP5 antibody in a panel transfected with Ubi-F, but the strong expression of the Ubi-N and Ubi-Z masked the endogenous signal in the adjacent cells. B, Cells were prepared for IIF 21 h after transfection with the full-length ubinuclein, Ubi-F. A and B, Ubi-F overexpression makes the transfected keratinocytes migrate from the basal cell layer, spread on the top of the basal cell layer, and finally disintegrate and shed off. C, EB1 overexpression downregulates the immunodetectable endogenous ubinuclein. Primary keratinocytes transiently transfected with the EB1 expression construct under the CMV promoter showed strictly nuclear localization in IIF for the EB1 protein. Only in a mitotic cell (see EB1 ab, green cell on the left) EB1 is temporarily released from the nucleus. D, The coexpression of EB1 and Ubi-F results in the cytoplasmic colocalization of EB1 and Ubi-F proteins. ZAP5 antibody was used to detect the ubinuclein protein (Texas red, A–D); M2 antibody was used to detect the Flag-epitope–tagged recombinant proteins (FITC, green, A and B); EB1 protein was detected with antibody A Z125 and visualized with anti-mouse–FITC (green, C and D). DNA in nuclei is demonstrated with DAPI staining and triple filter (blue staining in A–D). Bars, 10 μm.
interact with GST-Ubi-Z/ZAP5. As shown in Fig. 9 B, Z 306 did not bind to Ubi-Z/ZAP5 at all (Fig. 9 B, lane 7) and Z 310 bound only weakly (Fig. 9 B, lane 8), whereas Z 311 bound as avidly as the wild-type EB1 (Fig. 9 B, lane 9). Thus, within the bipartite basic domain of EB1, the basic amino acid residues are essential for binding, but an alanine to lysine substitution between the two basic regions did not affect the binding.

As shown above, EB1 interacts directly in vitro with Ubi-Z/ZAP5, and although the dimerization domain is required, this binding seems to involve specific residues in the region rich in basic amino acids. Therefore, we evaluated if this interaction was restricted to EB1 or if ubinuclein might also interact with other members of the bZIP family of proteins. As shown in the in vitro pull-down assay (Fig. 10 A), GST-Ubi-Z/ZAP5 showed significant affinity to the in vitro-translated EB1, to its derivative ZJ (the basic domain of EB1 replaced by the c-jun basic domain), and to C/EBP, whereas GST alone did not show interaction.

Since ubinuclein appeared to interact with the bZIP protein basic domain, which makes direct contact with DNA, we postulated that Ubi-Z/ZAP5 might impair the binding of EB1 to DNA. Indeed, an EMSA, increasing amounts of the in vitro-translated Ubi-Z/ZAP5 impaired the binding of in vitro-translated EB1 to an oligonucleotide containing an AP1 consensus binding site (Fig. 10 B). Since the dimerization domain of EB1 is essential for the formation of Ubi-Z/ZAP5-EB1 complex in vitro, we examined whether specific amino acids within the dimerization domain were required for the formation of this complex. The dimerization domain of EB1 was replaced by the homodimerization domain of the yeast transcriptional activator, GCN4. The in vitro-translated hybrid protein EB1\textsuperscript{GCN4} bound to the AP-1 consensus oligonucleotide, and the complex formation was competed by increasing amounts of in vitro-translated Ubi-Z/ZAP5 (Fig. 10 B). Collectively, our results strongly suggest that the dimerization of EB1 is necessary for the binding, whereas critical amino acid residues within the basic domain of EB1 are specifically involved in binding to ubinuclein.

Discussion

In this study, we report the molecular cloning and biological characterization of a novel gene actively expressed in a variety of tissues and cell lines. The protein is able to bind directly to both viral and cellular transcription factors, and both the endogenous protein and Flag-tagged recombinant protein encoded by an expression construct show nuclear localization. Hence, the protein was termed ubinuclein (ubiquitously expressed nuclear protein), and the corresponding human gene was termed UBN1. A most interesting morphological observation in keratinocyte cultures was that transfection with the full-length ubinuclein construct (Ubi-F) was associated with migration and spreading of the cells in vitro. The spread-out, flattened cells showed ubinuclein staining, in addition to nucleus, also in the cytoplasm. Eventually, these cells appeared to disintegrate and shed off from the top layer of the cultured cells. These observations, which were only noted with the full-length construct, but not with shortened constructs (Ubi-N and Ubi-Z), suggest a selective and specific biological role for ubinuclein in the differentiation of epidermal keratinocytes.

Ubinuclein Is Ubiquitously Expressed in Various Tissues

Ubinuclein is actively transcribed in essentially all tissues and cells, a notion supported by abundance of cDNA clones in the EST database. The high degree of homology between EST sequences representing different species and especially including the sequences within the 3'-UTR suggests potential importance for this novel transcript and the corresponding protein. The usage of two alternative promoters, characterized from the genomic DNA sequence and detected within the mRNA population through RT-PCR analysis, suggests the possibility for tissue-specific and constitutive or inducible expression of the transcripts.

Ubinuclein Shares Structural Features with Nuclear Proteins

The isolation of a cDNA clone encoding a partial ubinu-
Ubinuclein is a novel nuclear protein with specific domains that allow its binding with RNA, DNA, and proteins. It shares features with nuclear proteins.

**Viral versus Cellular Transcription Factors**

The EBV E1 protein is a transcription factor belonging to the bZIP family of nuclear proteins, which serve as components for dimeric transcription factors collectively called A P1 (Speck et al., 1997). Our results showed that in vitro-translated ubinuclein (Ubi-Z/ZAP5) prevented E1 binding to DNA. The dimerization of E1, either through the authentic dimerization domain or through the GCN4 dimerization domain, is a prerequisite for binding. Specific amino acid residues in the E1 dimerization domain are not essential for the in vitro interaction between ubinuclein and E1. Rather, it seems that a specific configuration of the basic domain imposed by the dimerization event is the prerequisite for binding. Recently, a nuclear chaperone regulating the dimerization of bZIP proteins has been characterized (Virbasius et al., 1999). A possible function for ubinuclein in vivo might be that it acts as a chaperone for bZIP factors, in which case ubinuclein mediates impairment of E1 and E1-like binding to DNA. It has been shown that phosphorylation of a serine residue at position 186 in the basic domain of E1 by protein kinase C, although it impairs E1 binding to DNA in vitro, increases E1-mediated activation of transcription (Baumann et al., 1998). Other cellular bZIP proteins are also regulated by phosphorylation/dephosphorylation at or near the basic domain (see references in Karin, 1994; Su and Karin, 1996). Whether ubinuclein is an active coregulator in these processes remains to be evaluated.

The immediate early transcription factor E1 is responsible for the initiation of the lytic cycle of E1V in human epithelial keratinocytes. Overexpression of the E1 in primary keratinocytes in culture seemed to downregulate the level of the endogenous ubinuclein. The consequence of the overexpression of ubinuclein, after the initial nuclear and nucleolar localization, was seen as the cytoplasmic distribution of the protein, followed by spreading and shedding of the transfected cells, which resembled the premature terminal differentiation event. The overexpression of transfected ubinuclein in the same cell with E1 resulted in the cytoplasmic distribution of E1 as well. These results suggest that ubinuclein and E1 are able to interact in vivo, which was detected as colocalization, and is responsible for redistribution of otherwise exclusively nuclear E1 protein. Cellular concentration, as well as distribution, of E1 and ubinuclein proteins may be important factors in the reactivation of the productive cycle in latently infected epithelial cells.

We thank Kyle Rothenberger for excellent technical assistance, Dr. Hans-Jürg Aieder (Kimmel Cancer Center, Thomas Jefferson University) for DNA sequencing, and Sue Gotta for immunofluorescence imaging. Dr. M. Inoue Bina (Purdue University), Dr. U. Irish Rodock (Thomas Jefferson University), and Dr. C. Gerd Maal (Wistar Institute) are acknowledged for helpful discussions.
