TO THE EDITOR: Dawson et al. (March 28 issue) suggest that the detection of circulating tumor DNA in 58% of patients with metastatic breast cancer can be used as an effective indicator of tumor load during treatment with standard systemic therapies. The study does not address the clinical utility of circulating tumor DNA. Moreover, the authors claim that circulating tumor DNA represents a more effective monitoring tool than the enumeration of circulating tumor cells. This statement is incorrect, considering that the enumeration of circulating tumor cells proved the ability to predict prognosis and monitor treatment efficacy in all patients with metastatic breast cancer, regardless of disease subtype. Furthermore, new detection methods describe the molecular heterogeneity and measure dynamic phenotypic changes in circulating tumor cells during metastasis. We propose that circulating tumor DNA provides a complementary method in the assessment of patients with detectable mutations and should be more appropriately used to select and monitor molecularly targeted therapies. Combined diagnostic methods will provide a more effective approach than each method alone to the implementation of precision medicine and improved clinical outcomes.

THE AUTHORS REPLY: We support the idea that combined methods involving circulating tumor cells and circulating tumor DNA could be used to analyze tumor status and changes. By the criterion of sensitivity for detection of disease burden, our data clearly show an advantage to the
Detection of circulating tumor DNA over the enumeration of circulating tumor cells by means of the CellSearch System. Our findings provide the rationale for future studies to address the full clinical utility of analyses with circulating tumor DNA.

One apparent limitation of our work was that only two genes (PIK3CA and TP53) were analyzed for most patients. These are the two most commonly mutated genes in breast cancer, and as expected, they were informative in half the patients recruited. This does not represent a general limitation of circulating tumor DNA: as a proof of principle, we also found that we were able to monitor other somatic mutations and structural variants in a subset of patients who did not have mutations in PIK3CA or TP53. Our data indicate that any cancer-specific mutation can be monitored in circulating tumor DNA from patients with metastatic breast cancer.

The timing of blood and plasma collection is obviously an important variable. In our study, all samples were collected immediately before the administration of each treatment cycle. The possibility of measuring an increase in the release of circulating tumor DNA as an indicator of responsiveness is attractive and is supported by xenograft models.1

Globalization, Climate Change, and Human Health

TO THE EDITOR: The scholarly review of globalization and climate change by McMichael (April 4 issue)1 emphasizes the associated economic, social, demographic, and environmental threats to human health and suggests steps to mitigate these changes on a global scale. Although McMichael also mentions the effects of climate change and globalization on the geographic range of vectorborne infections, he does not alert readers to sobering examples of the emergence of tropical infections in the temperate zone (Table 1). Globalization and climate change promote the emergence of these infections synergistically. Globalization increases the number of infected travelers and the accidental importation of infected vectors. Climate change warms the environment to temperatures that permit reproduction of the vector and parasite. Increasing
