## Abstract

The relationship between circadian phototransduction and circadian-regulated processes is poorly understood. Melatonin, commonly a circadian phase marker, may play a direct role in a myriad of physiologic processes. The circadian rhythm for pineal melatonin secretion is regulated by the hypothalamic suprachiasmatic nucleus (SCN). Its neural source of light input is a unique subset of intrinsically photosensitive retinal ganglion cells expressing melanopsin, the primary circadian photopigment in rodents and primates. Action spectra of melatonin suppression by light have shown that light in the 446–477 nm range, distinct from the visual system's peak sensitivity, is optimal for stimulating the human circadian system. Breast cancer is the oncological disease entity whose relationship to circadian rhythm fluctuations has perhaps been most extensively studied. Empirical data has increasingly supported the hypothesis that higher risk of breast cancer in industrialized countries is partly due to increased exposure to light at night. Studies of tumor biology implicate melatonin as a potential mediator of this effect. Yet, causality between lifestyle factors and circadian tumor biology remains elusive and likely reflects significant variability with physiologic context. Continued rigorous empirical inquiry into the physiology and clinical implications of these habitual, integrated aspects of life is highly warranted at this time.

## Introduction

The relationship between circadian phototransduction, endogenous melatonin levels, endocrine hormone physiology, and the myriad of normal and pathological circadian-regulated processes is far from being fully illuminated<sup>1,2</sup>. Many mutually consistent associations have been made between the light exposure history of an organism, circadian clock gene regulation, melatonin secretion, and the dysregulation of cell biology in cancer<sup>1,3</sup>, but the specifics of these relationships are still poorly understood. It is well established that light of sufficient intensity has an acute suppressive effect upon the

secretion of melatonin from the human pineal gland and that this suppression directly reflects the action of a non-visual photoreceptive system in circadian phototransduction<sup>4</sup>. The health implications of this suppressive potential of light upon melatonin, however, have only recently begun to be addressed.

Melatonin has been used frequently as a scientific marker of circadian phase<sup>5</sup>, or a biochemical marker of darkness<sup>6</sup>. Nevertheless, there is accumulating evidence that melatonin, as related to sleep/wake cycles and circadian physiology in general, may have a more direct role in several physiologic processes, spanning the fields of psychiatry, psychoneuroimmunology, oncology, and reproductive endocrinology<sup>7</sup>. For example, melatonin and circadian disturbance have been implicated in the pathophysiology of Seasonal Affective Disorder (SAD)<sup>7-10</sup>, and light therapy has been shown to be an effective treatment for this syndrome<sup>11-13</sup>. Low serum melatonin concentrations and urinary metabolite levels have also been found in women with estrogen-receptor positive breast cancer and men with prostate cancer<sup>14-16</sup>. More specifically, melatonin has been shown to have antiproliferative effects on neoplasms of several tissue types *in vitro* and *in vivo*<sup>17,18</sup>, to possess related antioxidant effects<sup>7,19-21</sup>, and to have immunostimulatory effects<sup>7,22</sup>.

Relatedly, some evidence suggests that alterations to endogenous reproductive hormone physiology, particularly the menstrual cycle length, may be a common pathway through which disruptions to melatonin and circadian rhythms affect breast cancer development and progression<sup>23</sup>. Animal studies have demonstrated that melatonin can, via influence upon gonadotropin-releasing hormone (GnRH) release in the hypothalamic–pituitary axis, affect gonadotropin (LH and FSH) release from the pituitary gland and, in turn, gonadal function. There is some indirect evidence in humans consistent with these findings, though the implications are still quite unclear<sup>21,24</sup>. For example, a correlation has been made between the stage of breast cancer and inversely proportional changes in nocturnal melatonin levels in breast cancer patients<sup>15</sup>. One study showed that the addition of melatonin to the traditional pharmacologic management of metastatic breast cancer appeared to slow disease progression<sup>21,25</sup>. Consistent findings have been shown in other cancer types<sup>21,26-27</sup>. Additionally, the oncostatic action of melatonin on human breast cancer has been linked to estrogen response<sup>21,28</sup>, with interactions occurring between melatonin and estradiol to influence breast cancer cell development<sup>21,29</sup>. This relationship between the hormones does not appear to be reciprocal, however, as it has been shown that the menstrual cycle phase and reproductive hormone status does not affect a woman's melatonin secretion<sup>7</sup> or sensitivity to melatonin suppression by light<sup>30</sup>.

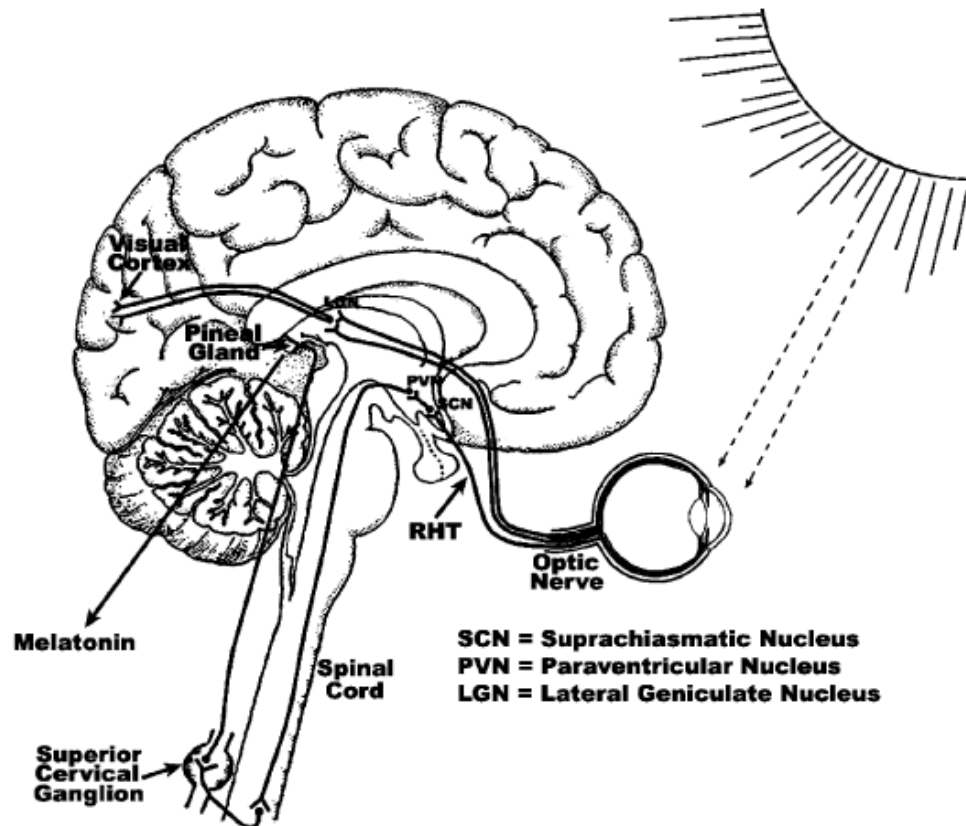

The complexity and importance of the interactions between light, the circadian system, and subsequent disturbances in hormone physiology and cancer is highlighted by the body of scientific evidence surrounding the relationship between light and breast cancer. Tissue-specific circadian clock organization in both normal and neoplastic proliferative tissue has the potential to accelerate tumor growth<sup>31</sup>. Similarly, the direction of melatonin rhythm entrainment to light stimuli as an advance or delay of the nighttime peak, is dependent upon the circadian time of the endogenous rhythm upon which the stimulus is superimposed<sup>32</sup>. This plasticity of response, however, like every other dynamic

physiologic process that occurs within the context of changing internal and external biological environments, is likely compounded by unique variations in response at different points along the pathways of light transmission. The concept of tissue-specific circadian programming via varied expression of clock genes is one mechanism of this plasticity, for example<sup>1</sup>. Regardless, any effort to begin clarifying this complexity is dependent upon an understanding of the incipient alterations that occur in the biological response to light, specifically, in circadian phototransduction.

### **The first dominos in the biological effect of light**

The circadian rhythm for melatonin secretion is regulated by the endogenously generated rhythm of the hypothalamic suprachiasmatic nuclei (SCN), via an indirect multi-synaptic pathway to the pineal gland. This intrinsic rhythm is, in turn, synchronized by light input from the environment to the SCN via the direct projections of the retinohypothalamic tract (RHT)<sup>33</sup>. A simplified diagram of the elements of this circuitry is shown in Figure 1. The source of these projections to the SCN is a unique subset of intrinsically photosensitive retinal ganglion cells (ipRGCs)<sup>34-37</sup>, and these intrinsically photosensitive ganglion cells have been shown to be in the same subset of retinal cells that express melanopsin<sup>38-39</sup>.

Initially, the search for an alternate circadian photoreceptor included both opsin-based molecules such as RPE-retinal G protein-coupled receptor, peropsin, encephalopsin, and melanopsin as well as non-opsin molecules like cryptochrome<sup>40</sup>. Cryptochrome was an early candidate as a nonvisual photoreceptor in mammals since it plays a central role in circadian photoreception in lower species<sup>41</sup>. Current evidence, however, suggests that the two cryptochrome homologs found in the inner retina of mammals are not strictly required for mammalian circadian phototransduction, but may have an accessory function in inner retinal phototransduction<sup>42</sup>.

**Fig. 1** Light influences melatonin secretion from the pineal gland via a multi-synaptic, indirect neural circuit. Light enters the eye through the pupillary aperture, stimulates the retina and sends its signal to the circadian pacemaker, the SCN, via a direct retinohypothalamic projection (RHT). Not shown here is the accessory connection between an integrating center in the thalamus, the intergeniculate leaflet (IGL), and the SCN. The IGL provides a second neural pathway for light to influence the circadian pacemaker. From the SCN, impulses travel to the pineal gland by first synapsing at the paraventricular nucleus of the hypothalamus, descending to synapse in the interomediolateral cell column (IMLCC) of the upper thoracic spinal cord, projecting to the superior cervical ganglion, and finally ascending along the cerebral vasculature to its final synapse at the pineal gland<sup>33</sup>

Recent evidence has confirmed that melanopsin is a primary photopigment mediating circadian phototransduction in rodents and primates<sup>43-46</sup>. Specifically, cells which are inherently incapable of photoreception were rendered photoreceptive after heterologous expression of human melanopsin<sup>43-46</sup>. It has been shown that the ipRGCs in rats and monkeys will depolarize in response to light with a peak spectral sensitivity around 480 nm, even with the blockage of synaptic input from rods and cones<sup>34</sup>. Furthermore, studies in rodents with retinal degeneration have indicated that neither the rod nor cone photoreceptors necessarily participate in circadian responses to light, including melatonin suppression and photoperiodic response<sup>47-49</sup>. Thus, both the anatomical distribution and physiologic profile of melanopsin indicate that this photoreceptive system is a

fundamental gateway for influencing the SCN's perception of light stimuli in the environment, and consequently, the responses of many dependent biological processes.

The acute suppression of plasma melatonin by light is a well-defined means of measuring the sensitivity of this non-visual photoreceptive system<sup>4,50</sup>, regardless of any downstream effects of the synthesized melatonin. Action spectra of melatonin suppression by light in healthy human subjects have shown that light in the 446–477 nm range is optimal for stimulating the circadian system and eliciting this suppression response<sup>51-52</sup>. This peak is distinct from the peak sensitivity of the three-cone photopic visual system, as well as each of the individual rods and cones for vision<sup>51-53</sup>. A study demonstrating that 460 nm monochromatic light is significantly more potent than 555 nm for phase-shifting the circadian pacemaker of healthy humans offers specific evidence to show that the peak sensitivity of the human circadian pacemaker is distinct from that of the classical three-cone system for photopic vision<sup>54</sup>. Figure 2 illustrates the two distinct photosensitivity inputs for vision and melatonin suppression.

**Fig. 2** Comparison of action spectra for the novel, melanopsin-based circadian photoreceptive system and the photopic, classical cone photoreceptors. The circadian action spectrum peaks in the 446–477 nm range, versus a 555 nm peak for the three cone visual system

Of note, however, it is apparent that the rods and cones, though not essential to the circadian response to light stimuli, appear to have a role in circadian photoreception under normal physiologic conditions. For example, retinally degenerate mice, while still maintaining the capacity for circadian photoreception and response to light, have a spectral sensitivity for circadian phase-shifting that is different from wild-type mice with normal functioning rods and cones<sup>55</sup>. There is also a residual phase shifting response in melanopsin genetic knock-out mice which suggests an alternate or redundant means for

light input to the SCN<sup>56</sup>. Studies in transgenic rodent models suggest that rod and cone photoreceptors have the capacity to transduce light for circadian regulation<sup>57</sup>. The extent to which these basic molecular findings in other mammals can be carried over in application to humans is still unknown, however the evidence to date in humans and non-human primates suggests there is a high level of correlation<sup>39,46</sup>. For example, it has been shown in humans that there is a bidirectional, mutual input potential between the novel, non-classical opsin-based photopigment and the classical rod-cone photoreceptors, where, under normal conditions, the novel circadian photopigment has a measurable role in rod and cone adaptation to light over time<sup>58</sup>. The SCN, itself, is also capable of receiving integrated neural information from the intergeniculate leaflet (IGL) of the thalamus, which itself receives retinal projections from the rod and cone visual system<sup>59</sup>. Thus, light has at least two neural pathways for stimulating the SCN in the process of entrainment, phase-shifting, or melatonin suppression. The light-induced regulation of melatonin or the broader circadian system can, in turn, potentially alter other physiologic processes downstream to a degree of magnitude which is still unknown.

The distinction between visual and circadian photoreception has been demonstrated on an empiric level as well. Blind persons who have no residual perception of light stimuli have nonetheless shown a melatonin suppression and circadian phase-shifting responses to bright light exposure<sup>60-61</sup>. Similarly, colorblind individuals appear to maintain this light-induced melatonin suppression<sup>62</sup>. The epidemiologic evidence showing a significantly decreased risk of breast cancer in women with profound bilateral blindness as compared with normally sighted women<sup>63-64</sup> suggests a correlation between these findings and the oncostatic properties of melatonin in the setting of cancer. Also supporting the idea of circadian melatonin regulation via a non-visual photoreceptive system as an endocrine link between light and reproductive hormone disturbances is the finding that blindness in human females is associated with an age of menarche that is earlier than normal and proportional to the level of light perception loss<sup>65</sup>.

Finally, although less sensitive than the visual system, circadian photoreception appears to be capable of responding to relatively low levels of light<sup>4,5,66-68</sup>. It has been shown in laboratory animals that indirect light as dim as 0.2 lux (0.06  $\mu\text{W}/\text{cm}^2$ ) has the capacity to significantly suppress nocturnal plasma melatonin levels and consequently increase hepatoma growth<sup>69-70</sup>. At the same time, however, circadian photoreception appears to involve a still poorly characterized and complicated method of integration of light stimuli over time by the photoreceptors themselves<sup>58</sup>, further downstream at the SCN<sup>71</sup>, and even more broadly on a tissue-specific level<sup>1</sup>. More recently, specific molecular findings are highly suggestive of melanopsin behaving more like an invertebrate opsin in nature than a vertebrate opsin and acting more like a photopigment than a photoisomerase influencing some other still-unknown opsin molecule<sup>58</sup>. The implications of these findings are far-reaching with regard to questions of photoreceptor adaptation and bleaching, for recent light history does appear to attenuate the response of subsequent melatonin suppression by bright white light<sup>72-73</sup>. Yet this varied circadian photoreceptive response throughout time cannot be accounted for by simple photon summation over the period of observation<sup>54</sup>. Summarily, it appears that circadian photoreception has specific spectral parameters for optimal response and a very low threshold for excitation, but

these characteristics cannot be accurately considered in isolation from their environmental, biological, and behavioral context.

## Circadian light measurement

With such a distinct photoresponse profile, it has become increasingly apparent that traditional means of light measurement do not suffice to provide an accurate point-in-time measurement of light input to the mammalian circadian system. For more than 25 years, research surrounding human circadian physiology has primarily used a photometric-based description and light measurement system<sup>5,74</sup>. The use of this measurement perspective, however, implies that the human visual (rod and cone photoreceptor) system is the primary system involved in circadian photoreception. A series of recent human experiments employing standard photobiological techniques have shown, specifically, that lux measurements are inappropriate for circadian, neuroendocrine, and therapeutic purposes. Specifically, equal photon doses of short-wavelength monochromatic light evoke a stronger acute melatonin suppression responses, circadian phase-shifts, core body temperature changes, subjective sleepiness, heart rate, auditory reaction time, and auditory lapses in human subjects, when compared with longer wavelength light at the peak of the photopic sensitivity curve<sup>51-54,75</sup>. The importance of this distinction in light measurement is demonstrated by the finding that, under optimum exposure conditions, as little as 5 lux of 460 nm light evokes an equivalent phase shift (3 h phase delay) when compared with 10,000 lux white fluorescent light<sup>54</sup>.

Thus, the characterization of light exposures for non-visual photobiological responses, including melatonin suppression, circadian phase-shifting, and tumor growth, should include radiometric quantification of irradiance and spectral power distribution<sup>76-77</sup>.

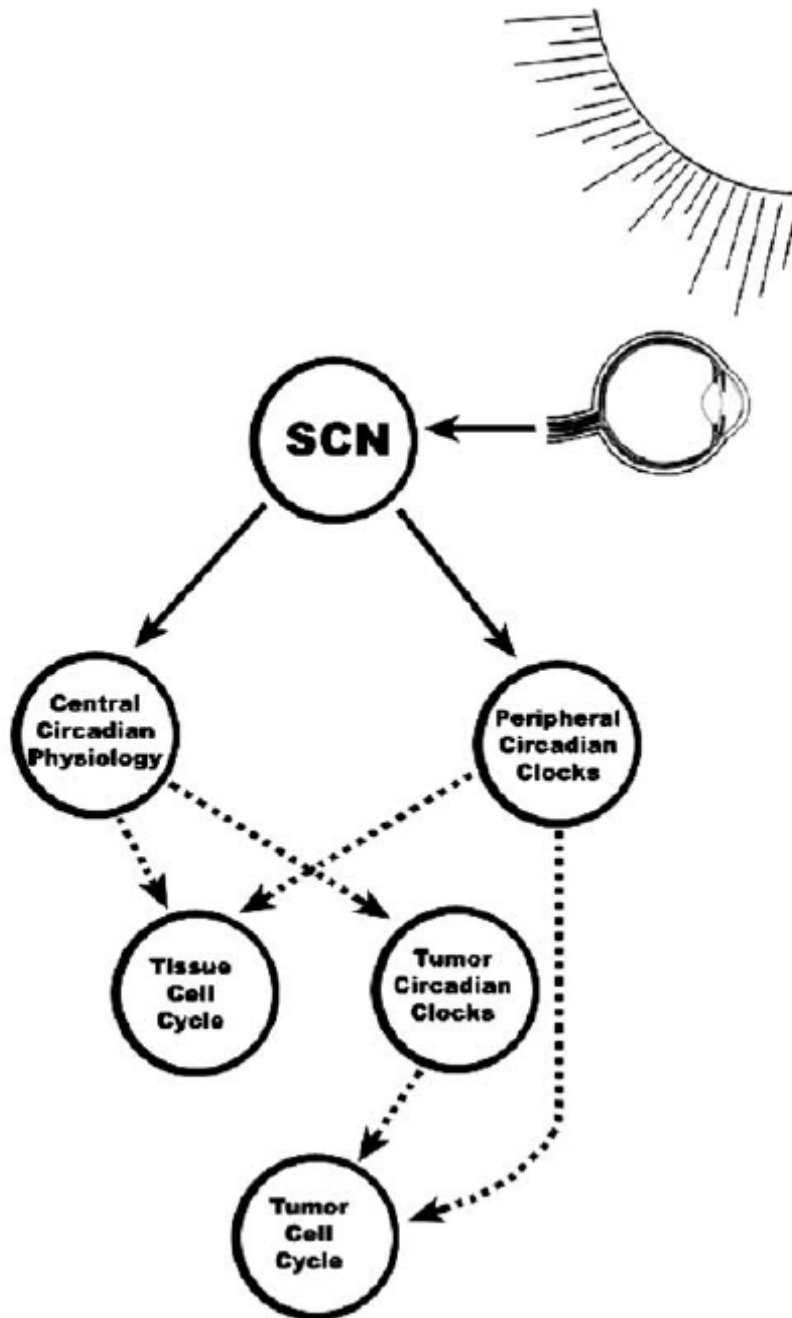

Furthermore, the implication of these findings for understanding the influence of various lighting conditions upon subsequent tumor development *in vivo* is to highlight the need for increased research conducted under conditions that emulate the daily photic environment of humans.

## The time of light

The circadian system's sensitivity to light stimuli varies immensely with both the circadian phase and the end effect being measured. It has been shown that practically all normal proliferating tissues have been shown to undergo circadian variation in DNA synthesis and mitotic index across a 24 h period, and similar variations appear to exist in tumor tissues depending upon the type and stage of growth<sup>31,78</sup>. Furthermore, as indicated in Figure 3, this tissue-specific rhythm is not necessarily directly reflective of broader, overarching circadian rhythms regulated by the biological master clock in the SCN<sup>1</sup>. Many anticancer agents have limiting cytotoxic effects on normal tissues that vary with cell proliferative activity and cell cycle stage<sup>78</sup>. Thus, an understanding of the characteristics of this circadian variation in response to a given light stimulus is highly germane to clarifying the relationship between light and cancer. Gaining utility of this

differential response of normal and neoplastic tissues to chemotherapy according to circadian state has the potential to maximize chemotherapeutic efficacy while minimizing toxicity. Advantages for circadian scheduling of chemotherapies have in fact already been shown to diminish side effects and increase the maximum tolerated doses for increased tumor response<sup>78</sup>.

**Fig. 3** Cell growth and division follows a tissue-specific program that is influenced by, but not homologous with, the SCN master clock rhythm. Solid arrows represent primary neural influence. Dotted arrows represent secondary synaptic influence. Figure adapted from Hastings, et al.<sup>1</sup>

## Light exposure during darkness and breast cancer

Breast cancer is the oncological disease entity whose relationship to circadian rhythm fluctuations has been brought most extensively to the attention of both clinical and basic science research. It has been shown that otherwise healthy women who are chronically subjected to nighttime shiftwork, and thus to light exposure at night, have a higher incidence of breast cancer<sup>79-80</sup>. Epidemiologically, the World Health Organization estimated in 1980 that half of all cancer in the world occurred in areas comprising one-fifth of the world's population, namely industrialized countries<sup>81</sup>. Thus, it has been hypothesized that the increased risk of breast cancer in industrialized countries is due, in part, to increased exposure to light at night, relative to unindustrialized countries who have significantly fewer nightshift workers<sup>23,82-83</sup>.

Increasingly, published empirical data has been supporting this hypothesis. Melatonin has been shown, at physiologic concentrations, to have a direct inhibitory effect on human breast cancer cells *in vitro*<sup>21</sup> and even more recently, *in vivo*<sup>18,84</sup>. It has also been established that light of sufficient intensity at night has the capacity to acutely inhibit the normal nocturnal rise in melatonin in humans<sup>4,21,85</sup>. This, in turn, would suggest that any environmental exposure which results in a relative decrease in integrated melatonin levels over time would consequently result in less oncostatic protection and a higher rate of breast cancer development and/or proliferation. This theoretical construct is consistent with epidemiologic findings<sup>80</sup>, as well as the melatonin-breast cancer hypothesis<sup>82</sup>. With acute light-induced melatonin suppression, however, there is likely to be coincident disruption of circadian phase and/or entrainment. Thus, it has not yet been determined if light exposure at night is a risk specifically due to acute melatonin suppression, to circadian disruption, or both.

The majority of studies have demonstrated a marked stimulatory effect of either pinealectomy or constant light exposure on tumor development and growth<sup>21,86</sup>. In general, following pinealectomy or exposure to constant bright light, not only do tumors appear earlier, but a greater percentage of animals develop tumors and more tumors develop per animal as compared to control animals maintained on an alternating 12 h light:12 h dark cycle. Although constant light exposure seems to stimulate tumorigenesis in the majority of investigations, clearly one-third of the studies conducted report either inhibitory, mixed or no effects on the development of experimental cancer. Interestingly, more consistent stimulatory actions of continuous illumination appear to occur with respect to the growth of established tumors<sup>86</sup>. In rats bearing either tissue-isolated rat liver cancer (i.e., hepatoma) or rat mammary cancer, constant bright light exposure (i.e., 300 lux at eye level) for one week prior to tumor implantation and continuing thereafter, completely suppresses the nocturnal, circadian rise in circulating melatonin levels, as compared with L:D controls. Tumors appear much earlier as a result of constant light exposure and their average daily growth rate accelerates by a factor of 2.5–6 times over the average growth rate of tumors in the L:D control group. The marked increase in the rates of tumor growth results from a substantial augmentation in the rate of tumor uptake

of linoleic acid (LA) and its conversion to 13-hydroxyoctadecadienoic acid (13-HODE) as a consequence of the suppression of the circadian melatonin signal<sup>69-70,87</sup>.

The ability of ocular light exposure to suppress pineal melatonin production depends on the intensity, wavelength, duration, and timing of light. As important as the constant bright light studies are, they address only one aspect of the intensity issue. Previous studies have demonstrated that the exposure of rats to low intensity fluorescent light (i.e., 0.2 lux at rodent eye level) during the dark phase for one week prior to the implantation of tissue-isolated rat hepatomas, results in a nearly complete suppression of circulating melatonin levels. Interestingly, the tumor growth rate, LA uptake, and metabolism to 13-HODE are nearly as rapid as in constant light-exposed animals, indicating that low intensity light-induced melatonin suppression during the dark phase is as effective as constant light exposure in tumor growth and LA metabolism<sup>69-70</sup>. Even more recent studies have examined the effects of different light intensities during darkness on nocturnal circulating melatonin levels and the growth and LA metabolism of rat hepatoma 7288CTC<sup>88</sup>. Exposure of tumor-bearing rats to fluorescent light intensities (at rodent eye level) ranging from complete darkness to constant bright light (345  $\mu\text{W}/\text{cm}^2$  or ~840 lux) results in a dose-dependent suppression of melatonin levels with a concomitant dose-related stimulation of tumor growth, LA uptake and 13-HODE production<sup>88</sup>. These findings represent the first evidence that stimulation of tumor growth and metabolism is dependent on the degree of the suppression of melatonin production that is, in turn, dependent upon the intensity of light present during darkness. Studies are currently examining fluence–response issues relative to melatonin suppression and the growth and LA metabolism of human breast cancer xenografts in nude rats. Furthermore, other ongoing studies are focusing on the role of the nocturnal, circadian melatonin signal, and its suppression by light during darkness in human volunteers, on human breast cancer xenograft growth and LA metabolism.

The light-melatonin-breast cancer hypothesis, with specific regard to human breast carcinogenesis, has not been directly addressed until recently. This has been done using a strain of athymic female rats in which human breast cancer xenografts grow quite well. During a two week period following their transfer from a 12L:12D light:dark cycle (i.e., intact circadian melatonin signal) to constant 300 lux bright light (i.e., no nocturnal melatonin signal), the average daily rate of tumor growth in constant light-exposed rats increased by seven-fold in comparison to the tumor growth rate in animals remaining on an L:D cycle. This accelerated rate of human breast cancer growth was initiated and sustained as a result of increases in the rate of tumor uptake of LA and its metabolism to 13-HODE. This augmented rate of tumor LA uptake and metabolism resulted from constant light-induced suppression of the circadian melatonin signal which normally drives the inhibition of these processes during the dark phase<sup>84</sup>. This is the first experimental evidence to date showing a link between inappropriate exposure to continuous bright light and increased growth and fatty acid metabolism of human breast cancer.

Thus, a better understanding of the photobiology underlying the effects of light upon endogenous melatonin rhythm offers potential to further scientific understanding of the

development and maintenance of oncologic processes. More specifically, the response of this dynamic system to changes in light intensity, spectral quality, and varied light exposure history is highly germane to gaining a better understanding of the potential relationships between light exposure and cancer risk. Elucidating the underlying photic input physiology to the pineal gland and subsequent melatonin regulation may provide a common doorway to influence both normal neuroendocrine homeostasis as well as oncological processes. Ultimately, rationally integrated lifestyle approaches may one day be used to prevent the development of some breast cancers as well as to restore health in some cancer patients.

## Conclusion

Concomitant molecular and empiric investigations of the relationship between light and cancer have begun to scratch the surface of this clinically expansive area of research. Still, clinical applications and shifts in theoretical structure are slow to follow scientific developments, and there is much room for future investigations to begin clarifying these ideas and give form to this promising evidence. For example, from a purely clinical perspective, etiologic theorizing concerning human breast cancer has centered primarily upon estrogen, its receptors, and the genetic inheritance of traits that influence their relationship. Currently, a patient's integrated estrogen exposure over time is perhaps one of the most exigently debated breast cancer risk factors. Accordingly, the personal historical elements which are most commonly analyzed in the primary survey of a patient's risk and/or prognosis for breast cancer include: age at onset of menarche and menopause, age of first term pregnancy and number of pregnancies, as well as personal and family history of pre-menopausal breast cancer<sup>89-91</sup>. In contrast, the patient's sleep/wake cycle, melatonin rhythm, light history, and work schedule are not typically considered as being relevant to this cancer risk assessment, in spite of the growing body of evidence supporting this possibility.

While accumulating evidence points toward potential for the various work schedule and lifestyle factors to influence tumorigenesis and progression, causality remains elusive and likely reflects significant variability with physiologic context. For example, it seems that the pathway by which melatonin influences tumor development and progression is dependent upon fatty acid availability and metabolism<sup>18,70</sup>. High fat consumption has not been consistently correlated with an increased risk of breast cancer in humans<sup>92</sup>, but increased constitutional fat content in obese females is correlated with higher levels of endogenous estrogen, which may, in turn, be the effector that potentiates many gynecologic neoplasms, such as breast cancer<sup>93</sup>. Furthermore, dietary constituents have been correlated with increased risk of other cancers, but the molecular players within this risk are yet to be consistently identified<sup>92,94</sup>.

Light exposure, the status of physiologic circadian rhythms, diet<sup>95</sup>, and exercise habits<sup>95</sup>, though recognized as bearing a potential influence on cancer outcome, are less well-defined in their roles in cancer pathophysiology and are consequently often given subordinate attention in clinical approaches to cancer<sup>96</sup>. Continued rigorous empirical inquiry into the physiology and clinical implications of these habitual, integrated aspects

of life is highly warranted at this time. Ultimately, when the weight of evidence becomes compelling, the traditions of clinical practice will be adjusted to reflect the relationship between light and cancer that current evidence suggests.
