Radiotherapy

ABSTRACT

Background: Hypoxia is associated with a poor prognosis in prostate cancer. This work aimed to derive and validate a hypoxia-related mRNA signature for localized prostate cancer.

Method: Hypoxia genes were identified in vitro via RNA-sequencing and combined with in vivo gene co-expression analysis to generate a signature. The signature was independently validated in eleven prostate cancer cohorts and a bladder cancer phase III randomized trial of radiotherapy alone or with carbogen and nicotinamide (CON).

Results: A 28-gene signature was derived. Patients with high signature scores had poorer biochemical recurrence-free survivals in six of eight independent cohorts of prostatectomy-treated patients (Log rank test \( P < .05 \)), with borderline significance achieved in the other two \((P < .1)\). The signature also predicted biochemical recurrence in patients receiving post-prostatectomy radiotherapy \((n = 130, P = .007)\) or definitive radiotherapy alone \((n = 248, P = .035)\). Lastly, the signature predicted metastasis events in a pooled cohort \((n = 631, P = .002)\). Prognostic significance remained after adjusting for clinic-pathological factors and commercially available prognostic signatures. The signature predicted benefit from hypoxia-modifying therapy in bladder cancer patients (intervention-by-signature interaction test \( P = .0026 \)), where carbogen and nicotinamide was associated with improved survival only in hypoxic tumours.

1. Introduction

Ninety percent of prostate cancer (PCa) patients are diagnosed with localized carcinoma, which have a highly variable course of disease progression. Hypoxia is a common micro-environmental feature in most solid tumours, which leads to changes in transcriptomic profiles, a higher potential to metastasise and resistance to radiotherapy [1]. Localized prostate cancer has marked and heterogeneous hypoxia [2], and hypoxia is an adverse prognostic feature [3–5]. Combining hypoxia-targeting treatment with radiotherapy was shown to improve local control of tumours and survival of patients in head and neck and bladder cancers [6–9]. There is good evidence from the literature that the most hypoxic tumours benefit the most from hypoxia-modifying therapy. However, there is no clinically validated method of selecting prostate cancer patients who would benefit from hypoxia modifying treatment.

Hypoxia gene signatures were successfully derived for multiple tumour sites including head and neck, bladder, soft tissue sarcoma and cervical cancers, which were not only independently prognostic but also predictive of benefit from hypoxia-modifying therapy in head and neck and bladder cancers [10–18]. Work in prostate cancer showed some prognostic significance for signatures derived in other tumour types [3] or associated with the hypoxia marker pimonidazole [15].

We previously showed that hypoxia gene signatures are better if tumour site specific [19]. The aim of this study was to generate and validate a prostate cancer-specific transcriptomic signature. In vitro analysis of genes regulated by hypoxia was combined with in vivo analysis of a gene co-expression network and patient survival using data from a retrospective cohort. Following signature derivation, validation was performed in multiple independent cohorts.

2. Methods

2.1. Patient Cohorts

This study included patients with prostate carcinoma from twelve cohorts, including the cancer genome atlas project (TCGA) [20], GSE54460 [21], GSE21032 [22], CPC-GENE [23], Cambridge [24,25], six retrieved from the Decipher GRID™ prostate cancer database [26–31], and one from Belfast [32]. A summary of the cohorts and procedures for pre-processing of transcriptomic data are provided in Supplementary Table 1 and Supplementary Methods. Patient cohort characteristics are summarised in Supplementary Table 2. The TCGA cohort was used as the training cohort. In addition, bladder cancer patients enrolled in a randomized trial of hypoxia-modifying therapy were available in the BCON cohort [6,18]. Informed consent protocols were approved by local Institutional Review Boards.

2.2. Endpoints and Statistical Analysis

Biochemical recurrence (BCR) free survival was the clinical endpoint of this study in all but one cohort. Distant metastasis (DMET) free survival was the clinical endpoint of the other cohort. Patient follow up data were censored at 5-year. The signature derived from this work assigned one hypoxia signature score for each individual tumour and in each cohort patients were stratified into high vs. low hypoxia based on the median cohort signature score. Survival estimates were performed using the Kaplan–Meier method. The Log-rank test was used to test the null hypothesis of equality of survival distributions. Hazard ratios (HR) and 95% confidence intervals (CI) were obtained using the Cox proportional hazard model. In case-cohort studies (originally designed to sample the adverse pathology population to estimate risk of metastasis after radical prostatectomy), randomly sampled sub-cohorts were used in order to reduce over-estimation of events in evaluation of the BCR endpoint. Odds ratios (OR) were obtained using logistic regression models. Association between hypoxia signature score and Gleason group, tumour stage was estimated using simple linear regression. All P-values were two sided and statistical significance was set as 0.05.

2.3. Prostate Cancer Hypoxia Signature Development

A network-based methodology was applied for generation of a prostate cancer-specific hypoxia signature, hypothesising that in vitro hypoxia regulated genes co-expressing with each other in vivo collectively indicate tumour hypoxia. Briefly, genes up- and down-regulated by hypoxia (1% O2, 24 h) were identified with RNA sequencing in four PCa cell lines (PNT2-C2, LNCaP, DU-145, and PC-3). The four cell lines were chosen as they were derived from human tissues and are widely used as in vitro PCa models [33]. A gene co-expression network was constructed in a TCGA training cohort and a putative gene module enriched with in vitro hypoxia genes was identified. Genes within the putative module were ranked by their connectivity and added iteratively into the signature. The final signature was selected based on prognostic significance. The signature scores are a continuous variable, which were then binarised into high and low categories using the median value for each cohort. The hypoxia signature derived here was then independently validated in the other eleven PCa cohorts. In multivariable analysis, the hypoxia gene signature was adjusted for standard clinicopathological factors and a genomic classifier Decipher [27]. More details were given in Supplementary Methods.

2.4. Comparison with Literature Transcriptomic and Genomic Signatures

Seven hypoxia [10,11,14–17] and eleven prostate cancer transcriptomic signatures [34–44] were curated from the literature and their prognostic significances were evaluated for comparison (Supplementary methods). Furthermore, the potential benefit of combining the de-novo hypoxia signature with a prognostic 31-loci DNA classifier [45] was also investigated by entering both into a Cox model.

3. Results

3.1. In Vitro Hypoxia Responsive Genes

Genes up or down regulated under hypoxia in four PCa cell lines were identified. 84, 306 and 848 genes were differentially expressed in greater than four, three and two cell lines, respectively. A seed gene database was constructed consisting of the 848 genes differentially expressed in two or more cell lines (Supplementary Table 3). Eight cell cycle and metabolism pathways were enriched in the hypoxia seed gene dataset (Supplementary Table 4). For many of the above identified genes, their regulation under hypoxia was well documented [46,47].

3.2. In Vivo Prostate Cancer-Specific Hypoxia Gene Module

A PCa gene co-expression network was built from pre-treatment tumour biopsies in the TCGA cohort. The network, containing 1836 genes (including 113 seed genes) of good variability was partitioned into 34
gene modules. One module of 66 genes was identified most hypoxia-related as 33% of its member genes (22/66, \( P = 4.85 \times 10^{-12} \), Supplementary Fig. 1) were seed genes. Another 24 genes from the 66-gene module were hypoxia regulated in one cell line (Supplementary Fig. 2). The final signature, containing 28 genes from the 66-gene module, was derived by evaluating prognostic significance in cross validation. The signature gene coefficients were determined from a Cox survival model (Supplementary Table 5). Patients with high signature scores were associated with significantly poorer outcome (log rank \( P = 1.9 \times 10^{-8} \), Supplementary Fig. 3).

3.3. 28-Gene Signature Is Prognostic of BCR in PCa Cohorts Receiving Radical Prostatectomy

The high correlation among the 28 hypoxia signature genes was well preserved in the independent validation cohorts (Supplementary Fig.
suggesting the good reproducibility of the signature. The 28-signature genes also clustered tumours in independent validation cohorts into two clear groups (Supplementary Figs. 5 and 6).

The 28-gene signature and all coefficients were frozen and applied to independent validation cohorts. The prognostic value of the 28-gene hypoxia signature was first validated in the GSE21032 (fresh frozen), GSE54460 (FFPE) and Cambridge (fresh frozen) prostatectomy cohorts. In both GSE21032 and GSE54460, tumours with high 28-gene signature scores were associated with significantly poorer 5-year BCR in the GSE21032 (n = 131, HR 4.59, 95% CI 1.71–12.32, P = .0025, Fig. 1A) and GSE54460 (n = 106, HR 2.12, 95% CI 1.20–3.74, P = .0098, Fig. 1B) cohorts. In the Cambridge cohort, borderline prognostic significance was observed with the default median cut-off signature score (n = 111, HR 2.54, 95% CI 0.96–6.69, P = .06, Fig. 1C), which improved when an upper quartile split was used (HR 4.54, 95% CI 1.82–11.36, P = .0011). A continuous 28-gene signature score also achieved prognostic significance (P = .047) in the Cambridge cohort.

In other five prostatectomy-treated cohorts, tumours with high 28-gene signature scores were again associated with significantly poorer outcome (GSE79957: n = 260, HR 1.60, P = .055; GSE62116: n = 235, HR 2.04 P = .007; GSE41408: n = 48, OR 0.62, P = .0022; GSE62667: n = 182, OR 0.59, P = .0030; and CPC-GENE: n = 212, HR 1.80, P = .026, Fig. 1D to H).

Multivariable analysis was performed adjusting the hypoxia signature with clinicopathological covariates and the Decipher genomic classifier, wherever possible (Table 1). Statistical significance was retained in three cohorts (GSE21032: HR 3.51, P = .021; GSE4460: HR 1.84, P = .048; and CPC-GENE: HR 1.81, P = .021), and was borderline in another two cohorts (GSE62116: HR 1.36, P = .059; and GSE41408: OR 2.89, P = .081).

### 3.4. 28-Gene Signature is a Strong Independent Prognostic Factor in PCa Cohorts Receiving Radiotherapy

The 28-gene signature predicted biochemical recurrence in the GSE72291 cohort treated with post-operative radiotherapy (n = 130, HR 2.81, 95% CI 1.33–6.00, P = .007, Fig. 2A). In multivariable analysis (Table 2), the hypoxia signature remained a strong prognostic factor (HR = 2.17, P = .014) alongside Decipher (HR = 2.24, P = .0061), Gleason group 5 (HR 8.50, P = .0012), and pre-treatment PSA level (HR 1.74, P = .0042). The hypoxia signature was also prognostic in the Belfast cohort of intermediate/high-risk patients who underwent definitive radiotherapy (n = 248, log rank P = .035, Fig. 2B). Multivariable analysis was not performed due to the low event rate.

### 3.5. 28-Gene Signature Predicts Metastatic Outcome

The 28-gene signature was also evaluated in a pooled cohort of 631 PCa patients from four studies with metastatic outcome [29–31,48]. The signature predicted distant metastasis events with a HR of 2.41 (95% CI 1.38–4.19, P = .002). In multivariable analysis, the hypoxia signature remained significant (HR 2.57, 95% CI 1.38–4.77, P = .003) alongside Decipher, seminal vesicle invasion and lymph node invasion (Table 3).

### 3.6. 28-Gene Signature Is Associated With Gleason Score and Tumour Stage

A positive and significant correlation was seen between the 28-gene signature score and pathological Gleason score in five of the six examined cohorts (Supplementary Fig. 7). Hypoxia score increased significantly with tumour stage in four of the six cohorts (Supplementary Fig. 8), but was not associated with pre-treatment PSA (Supplementary Fig. 9). In GSE21032, the hypoxia signature scores were significantly higher in metastatic compared with primary tissue (P = .007, Supplementary Fig. 10).

3.7. Prediction of Benefit from Hypoxia Modification of Radiotherapy

The 28-gene prostate signature was further validated in the BCON phase III randomized trial of radiotherapy alone or with carbogen and nicotinamide (CON) for bladder cancer patients. Tumours were stratified as high or low from median, first, and third quartiles of cohort 28-gene signature scores. When the first quartile was used, high hypoxic tumours were associated with a non-significant trend of poor prognosis in patients treated with radiotherapy only (overall survival, \( n = 75 \), HR 1.68, \( P = .17 \), Supplementary Fig. 11). BCON tumours stratified as high hypoxic had improved survival with the addition of CON (\( n = 113 \), HR 2.49, 95% CI 1.06–5.89, \( P = .037 \), Supplementary Fig. 12). A signature-intervention interaction test confirmed the predictive value of the signature for both binary hypoxic status (\( P = .0026 \)) and continuous hypoxia score (\( P = .037 \)). CON was shown to have a detrimental effect on the treatment would only benefiting a subset of patients and might even produce adverse effect on others, this emphasized the importance of identifying reliable predictive biomarker.

3.8. Comparison with Literature Gene Signatures

The prognostic value of published hypoxia and PCa transcriptomic signatures were compared in both GSE21032 and GSE54460 (Supplementary Tables 9 and 10). Our 28-gene signature scores correlated moderately with nature \([16]\), derived for head and neck cancer, was prognostic in both cohorts. The Toustrup signature \([15]\), derived for head and neck cancer, was prognostic in both cohorts. Our 28-gene signature scores correlated moderately with Toustrup signature scores (GSE21032: Pearson \( r = 0.33, P = .0011 \); GSE54460: Pearson \( r = 0.51, P = 2.32 \times 10^{-4} \), Supplementary Fig. 13). The 28-gene signature had higher prognostic significance and was the only significant factor when both signatures were entered into a Cox proportional hazards regression model (Supplementary Table 8).

3.9. Association with Copy Number Alteration Burden and Genomic Classifier

Recent studies suggested global copy number alteration (CNA) burden as a prognostic marker of PCa patients \([22,49]\). A very moderate correlation was found between global CNA burden, defined as the percentage of the tumour genome affected by CNA, and hypoxia signature scores for both TCGA (Pearson correlation 0.36, Supplementary Fig. 14) and GSE21032 (Pearson correlation 0.40, Supplementary Fig. 14). Hypoxia signature (binary or continuous) and CNA burden (continuous) both retained significance when entered together into a Cox model in both cohorts (Supplementary Tables 9 and 10).

A 100-loci prognostic classifier for localized PCa \([3]\) was recently identified and reduced to a 31-loci signature \([45]\). Both reflect genomic instability and were shown to have high prognostic value in >500 prostate cancer patients. We examined if adding the 28-gene signature and genomic classifier could further improve prognostication for PCa.

patients. In the CPC-GENE cohort [23], the 28-gene signature (log rank $P = .023$, Fig. 1F) achieved similar prognostic significance compared with the 31-loci genomic instability classifier (log rank $P = .042$, Supplementary Fig. 15). Combining the 31-loci genomic classifier with the 28-gene signature improved prognostication (log rank $P = .0035$, Supplementary Fig. 16). Using patients with low 28-gene signature and low 31-loci signature as a reference, patients with high 28-gene signature and high 31-loci signature had a significantly poorer outcome (HR 2.75, 95% CI 1.42–5.31, $P = .0026$). Patients with only positive 28-gene signature ($P = .58$) or 31-loci signature ($P = .41$) had similar survival as the double negative group, respectively (Supplementary Table 11). The above analyses suggested that improved prognostication can be achieved by combining the 28-gene signature and indicators of genome instability, consistent with the previous observation from Lalonde et al. [3].

4. Discussion

A 28-gene signature was derived and shown to be independently prognostic in eleven cohorts of low- to high-risk prostate cancer patients with localized disease. Ten genes (ATF3, BHLHE40, SLC2A3, EGR1, KLF10, FOSL2, CYR61, SLC2A14, KLF6, and TIPARP) in the 28-gene signature were previously shown to be hypoxia regulated in different tumour sites (Supplementary Table 12). The study showed that the Toustrup hypoxia signature [16], prognostic and predictive of hypoxia-modifying therapy for head and neck cancer, was prognostic in prostate cancer patients. The Ragnum signature [15], the only prostate cancer-specific hypoxia signature in the literature, had (borderline) prognostic significance for biochemical recurrence. A moderate correlation was found between the Toustrup 15-gene and our 28-gene hypoxia signatures score.

The derived 28-gene signature could be combined with a recently published genomic classifier to identify a group of high-risk PCA patients with very poor prognosis. The 28-gene hypoxia signature has translational significance. The prognostic value of the signature was independently validated in seven cohorts of biopsies preserved in FFPE blocks, a routine technique for preserving tissues in hospitals. Degradation and chemical modification of nucleic acids in FFPE samples significantly reduces RNA quality. [50] The prognostic significance of the signature was also confirmed using three major high-throughput expression profiling platforms, i.e. Affymetrix array, Illumina BeadArray and RNA-seq. The results of the current study clearly indicate the robustness of the signature for routine clinical application.

One major limitation for the derived 28-gene signature is the lack of benchmarking against gold-standard hypoxia measurement with polographic needle oxygen electrodes. Prognostic information was used in the signature derivation procedure, therefore the final signature could reflect other poor prognostic parameters beyond hypoxia. Use of needle electrode presents great technical challenge, where to date the needle electrode presents great technical challenge, where to date the needle electrode presents great technical challenge, where to date the needle electrode presents great technical challenge, where to date the needle electrode presents great technical challenge, where to date the need
