Association of metabolic syndrome and change in Unified Parkinson’s Disease Rating Scale scores

**ABSTRACT**

**Objective:** To explore the association between metabolic syndrome and the Unified Parkinson’s Disease Rating Scale (UPDRS) scores and, secondarily, the Symbol Digit Modalities Test (SDMT).

**Methods:** This is a secondary analysis of data from 1,022 of 1,741 participants of the National Institute of Neurological Disorders and Stroke Exploratory Clinical Trials in Parkinson Disease Long-Term Study 1, a randomized, placebo-controlled trial of creatine. Participants were categorized as having or not having metabolic syndrome on the basis of modified criteria from the National Cholesterol Education Program Adult Treatment Panel III. Those who had the same metabolic syndrome status at consecutive annual visits were included. The change in UPDRS and SDMT scores from randomization to 3 years was compared in participants with and without metabolic syndrome.

**Results:** Participants with metabolic syndrome (n = 396) compared to those without (n = 626) were older (mean [SD] 63.9 [8.1] vs 59.9 [9.4] years; p < 0.0001), were more likely to be male (75.3% vs 57.0%; p < 0.0001), and had a higher mean uric acid level (men 5.7 [1.3] vs 5.3 [1.1] mg/dL, women 4.9 [1.3] vs 3.9 [0.9] mg/dL, p < 0.0001). Participants with metabolic syndrome experienced an additional 0.6- (0.2) unit annual increase in total UPDRS (p = 0.02) and 0.5- (0.2) unit increase in motor UPDRS (p = 0.01) scores compared with participants without metabolic syndrome. There was no difference in the change in SDMT scores.

**Conclusions:** Persons with Parkinson disease meeting modified criteria for metabolic syndrome experienced a greater increase in total UPDRS scores over time, mainly as a result of increases in motor scores, compared to those who did not. Further studies are needed to confirm this finding.

ClinicalTrials.gov identifier: NCT00449865. Neurology® 2017;89:1789-1794

**GLOSSARY**

ATP III = Adult Treatment Panel III; BMI = body mass index; NCEP = National Cholesterol Education Program; NET-PD LS 1 = National Institute of Neurological Disorders and Stroke Exploratory Trials in PD Long-Term Study 1; PD = Parkinson disease; SDMT = Symbol Digit Modalities Test; UPDRS = Unified Parkinson’s Disease Rating Scale.

Metabolic syndrome is a combination of conditions—hypertension, hyperglycemia, hyperlipidemia, and increased waist circumference—that, when occurring together, escalate a person’s risk for heart disease, stroke, and diabetes mellitus. Recent studies suggest that the syndrome is also associated with increased risk of other diseases, including Parkinson disease (PD).

However, studies on the association of metabolic syndrome and PD have yielded inconsistent results. For example, recent meta-analyses of the association of diabetes mellitus and the risk of developing PD had...
neurology 89 october 24, 2017

when an interim analysis determined that creatine had no effect March 2007 to September 2013. The study was terminated early, 10 mg creatine monohydrate vs placebo and was conducted from center, placebo-controlled, randomized, double-blind trial of previously.27 design and characteristics of the population have been reported were on dopaminergic therapy at randomization. The study did not.22 Higher body mass index (BMI) atered with an increased risk of PD in multiple studies16,18,25 but not in others.19,24 A recent study found that patients with PD with increasing BMI had slower PD progression than those with a stable or declining BMI25 as measured by the Unified Parkinson’s Disease Rating Scale (UPDRS). Another study reported that diabetes mellitus was associated with more rigidity and a parkinsonian-type gait in aging persons without a diagnosis of PD or dementia.26

To the best of our knowledge, the effect of metabolic syndrome on PD progression has not previously been studied. The aim of this study was to investigate the relationship between metabolic syndrome and progression of PD using change in UPDRS. Because metabolic syndrome may have a role in driving cognitive impairment in PD, we also explored the association of metabolic syndrome and a cognitive measure. Using data from the National Institute of Neurological Disorders and Stroke Exploratory Trials in PD Long-Term Study 1 (NET-PD LS 1),27 we compared the progression of PD in those who had metabolic syndrome throughout the first 3 years of the trial to those who were without evidence of metabolic syndrome.

METHODS Participants. NET-PD LS 1 was a large, multi-center, placebo-controlled, randomized, double-blind trial of 10 mg creatine monohydrate vs placebo and was conducted from March 2007 to September 2013. The study was terminated early, when an interim analysis determined that creatine had no effect on progression of PD.24 All participants had early-stage PD and were on dopaminergic therapy at randomization. The study design and characteristics of the population have been reported previously.27

The NET-PD LS 1 study enrolled a total of 1,741 participants. Each participant was categorized as having metabolic syndrome or not at baseline and 1-, 2-, and 3-year visits. As a result of missing data at any of these visits, we were unable to assess the metabolic syndrome status of 319 participants. Furthermore, only those who maintained the same metabolic syndrome status for consecutive visits were included. Four hundred participants experienced a change in their metabolic syndrome status during the first 3 years of the study and were excluded from the analysis. Therefore, of the 1,741 participants at baseline, 1,022 were included in the final analysis.

Standard protocol approvals, registrations, and patient consents. NET-PD LS 1 is registered on clinicaltrials.gov with identifier NCT00449865. The institutional review boards of each institution that participated approved the study, and all participants signed informed consent.

Outcome measures. As part of NET-PD LS-1, UPDRS scores for parts I, II, and III were assessed over time. Three outcome measures were used for this study from baseline to the 3-year visit. The primary outcome measure was the change in the total UPDRS score (which we define here as parts I + II + III) from the baseline (randomization) to the 3-year visit. The secondary outcome measure was the change in the motor UPDRS (part III) over the same time range. An additional outcome measure was the Symbol Digit Modalities Test (SDMT) score,23 which was the only cognitive test collected at annual visits.

Exposure. We categorized participants on the basis of the commonly agreed-on criteria from the National Cholesterol Educa- tion Program (NCEP) Adult Treatment Panel III (ATP III), which was updated in 2005.29 The NCEP criteria require 3 or more of the following to be diagnosed with metabolic syndrome: (1) waist circumference >35 in for women and >40 in for men, (2) serum triglycerides ≥150 mg/dL (1.7 mmol/L) or medication therapy for high triglycerides, (3) serum high-density lipoprotein cholesterol <50 mg/dL (1.3 mmol/L) in women and <40 mg/dL (1 mmol/L) in men or medication treatment for low high-density lipoprotein cholesterol, (4) blood pressure ≥130/85 mm Hg or on medication therapy for high blood pressure, and (5) fasting plasma glucose ≥100 mg/dL (5.6 mmol/L) or on medication therapy for high glucose.

Because the protocol for NET-PD LS-1 did not include waist measurements or collection of cholesterol, triglyceride, or fasting glucose levels, we adapted the ATP III criteria29 for use in our study.26 Metabolic syndrome was defined as having 2 or more of the following criteria: (1) BMI >30 kg/m²; (2) on statin mediation; (3) systolic blood pressure >130 mm Hg, diastolic blood pressure >85 mm Hg, or on antihypertensive medication; or (4) random blood sugar >120 mg/dL or on antihyperglycemic medication. Criteria were the same for both sexes. Participants who no longer fulfilled our modified criteria at subsequent visits were excluded from the analysis to avoid miscategorization bias. Using these modified ATP III criteria, participants were classified into 2 groups: participants who had metabolic syndrome throughout the 3 years of the study and participants who were without evidence of metabolic syndrome across all 3 years.

Statistical methods. Descriptive statistics (mean, SD, fre- quency, and percentages) were used to summarize the demo- graphics for 2 groups: metabolic syndrome and no metabolic syndrome. Differences in the mean or proportions between these 2 groups were checked by t test or χ² test.

The association of metabolic syndrome with the change in the total and motor UPDRS and SDMT scores across time was esti- mated with a linear mixed model. Because the randomization process included blocking by site, both site and treatment assignment (creatine vs placebo) were used as covariates.27

Metabolic syndrome, time in years, treatment group, and the interaction term of metabolic syndrome and time in years were tested in this model after adjustment for confounding variables: baseline age, baseline total UPDRS, sex, handedness, race, uric acid levels, and disease duration at baseline. Similarly, a second model was adjusted for motor UPDRS score, and the only differ- ence was the covariate baseline motor UPDRS instead of total UPDRS score as stated before. A locally weighted scatterplot smoothing plot for change in total UPDRS across time is pre- sented to show the differences by group. The SDMT analysis, using change in SDMT from baseline as the response variable,

RESULTS Table 1 shows the demographic characteristics of the participants for this study according to whether participants were categorized as having metabolic syndrome. Baseline mean age and mean uric acid levels were significantly different in these 2 groups, as well as the proportion of men and women in these 2 groups. Participants with metabolic syndrome were more likely to be men, to be older, and to have a higher mean uric acid level compared to those without metabolic syndrome.

Table 2 shows the change in total UPDRS over 3 years compared between the metabolic syndrome and no metabolic syndrome groups. On average, participants without metabolic syndrome experienced a 1.7-unit annual increase in total UPDRS score from their baseline values, while participants with metabolic syndrome experienced a 2.3- (1.7 + 0.6) unit annual increase in total UPDRS change from baseline after controlling for covariates. This information is also presented in the figure, which demonstrates that participants with metabolic syndrome were more likely to have increases in total UPDRS scores, especially in the third year of study.

Table 3 shows the change in motor UPDRS (part III) score, the secondary outcome measure, over 3 years compared between the 2 groups. On average, participants without metabolic syndrome experienced a 0.8-unit annual increase in their motor UPDRS score, while participants with metabolic syndrome experienced a 1.3- (0.8 + 0.5) unit increase per year.

Table 4 shows the change in SDMT. While the SDMT declined 0.2 units (standard error = 0.1) per year (p = 0.03), there was no significant difference, 0.3- vs 0.2-unit annual decline, between those with vs without metabolic syndrome (p = 0.77), respectively.

DISCUSSION This study shows that participants with early-stage, treated PD who met modified criteria for metabolic syndrome had more rapid progression as measured by both the total and motor UPDRS scores over time compared to those without metabolic syndrome. This finding is consistent with prior studies suggesting that the presence of metabolic syndrome is associated with increased risk of developing PD, Alzheimer disease, cognitive decline, and other diseases.1-8 We could find no other study...
showing an association between metabolic syndrome and progression of PD, so this finding needs confirmation. If confirmed, this would raise the possibility that improved treatment of metabolic syndrome could offer a novel approach to slowing PD progression.

How metabolic syndrome might accelerate PD progression is not known. Because metabolic syndrome is a combination of conditions, each of these conditions could contribute to the association. A recent analysis of the NET-PD population found that an increase in BMI was associated with a slower increase in UPDRS scores, so it seems unlikely that the high BMI component of metabolic syndrome contributes strongly to the association of metabolic syndrome and increasing UPDRS scores. Another metabolic syndrome condition, hypertension, could drive faster PD progression if it caused those affected to have more CNS ischemia or strokes. Brain imaging data were not collected in the NET-PD study, so this theory cannot be substantiated with our data. Regarding blood triglyceride, glucose, and high-density lipoprotein cholesterol levels, the literature to date is conflicting, lacking, or not informative. Insulin resistance and inflammation underlie metabolic syndrome, and these pathologic mechanisms also contribute to the progressive loss of dopaminergic cells that results in PD. The association found between metabolic syndrome and PD may therefore be attributed to common pathophysiologic pathways.

The faster progression of motor signs in our participants with metabolic syndrome compared to those without could be related to the accumulating evidence of brain abnormalities in the expression of insulin and insulin growth factors and their related receptors and CNS insulin resistance being reported in PD. Activities of insulin growth factors include support of neuronal growth and survival. Recent literature suggests that these insulin-related CNS abnormalities may increase sensitivity to neurotoxins and the accumulation of α-synuclein. While further studies are needed to judge whether these brain abnormalities correlate with clinical longitudinal signs, given that patients with PD have CNS insulin-related abnormalities that normally play a protective role, concurrent metabolic syndrome is likely to exacerbate these baseline abnormalities and to enhance the progression of disease.

While uric acid levels are not a defined component of metabolic syndrome, the syndrome is associated with higher uric acid levels. Studies to date suggest that higher uric acid levels are associated with more slowly increasing UPDRS scores. In this study, however, the metabolic syndrome group had higher uric acid levels and had faster increasing UPDRS scores.

The association of metabolic syndrome and cognitive function was explored in this study. In NET-PD, the only cognitive measure captured at annual visits was the SDMT score. There was no significant difference: 0.3- vs 0.2-unit annual decline in participants with metabolic syndrome vs without (p = 0.77).

However, this analysis was limited by the minimal decline in SDMT scores that occurred in this early treated PD group. Furthermore, the SDMT evaluates attention and not other cognitive domains or global cognitive function.

A strength of this study is that it is derived from a relatively large and well-characterized cohort. In addition, the results of the sensitivity analyses consistently generated the same result: those with metabolic syndrome had greater increasing UPDRS scores over time than those without metabolic syndrome. However, the conclusions are limited by the use of a modified definition of metabolic syndrome. Therefore, additional studies incorporating stricter measurements of the components of metabolic syndrome are required to confirm the findings of this initial study.

In NET-PD LS1, participants meeting criteria for metabolic syndrome experienced a greater increase in total UPDRS scores, mainly due to increases in motor scores, compared to those not meeting these criteria. If confirmed, future work should determine whether treatment of metabolic syndrome results in a slower increase in UPDRS scores over time.
