Dose-Response of Nitrous Oxide in Postoperative Nausea in Patients undergoing Gynecologic Laparoscopic Surgery – A Preliminary Study.

Short title: Dose-Response of nitrous oxide in PONV

Implications Statement:

We demonstrate that nitrous oxide (N₂O) increases the incidence of postoperative nausea after laparoscopic gynecologic surgery. The preliminary findings indicate that N₂O may increase PONV in dose dependant fashion. High concentration of N₂O in this clinical setting is not recommended.
Abstract:

**Background:** Whether nitrous oxide (N₂O) increases incidence of postoperative nausea and vomiting (PONV) after laparoscopic gynecologic surgery is still controversial. This uncertainty may be due to the administration of different concentrations of inspired N₂O. We investigated if N₂O results in a dose response increase in PONV.

**Methods:** Patients undergoing gynecologic laparoscopic surgery were randomized to receive 30% oxygen with air (G0, n=46), 50% N₂O with oxygen (G50, n=46) and 70% N₂O with oxygen (G70, n=45). A standardized general anesthetic was used with no PONV prophylaxis. Known risk factors for PONV were controlled. Metoclopramide was used as a rescue antiemetic. Incidence of nausea, vomiting, use of rescue antiemetic and pain VAS score were measured at 2 and 24 hours postoperatively.

**Results:** Patient demographics were comparable and there were no differences among groups with regards to factors that may influence PONV. Incidence of PONV at 24 hours was 33% (15/46) in G0 versus 46% (21/46) in G50 versus 62% (28/45) in G70 (p=0.018). Subgroup analysis revealed a difference between G0 vs G70 (p=0.018), but no significant difference between G0 vs G50 and G50 vs G70. The incidence of nausea showed a similar difference (G0=26%, G50=35% and G70=56%; p=0.012), but the incidence of vomiting was not different between the groups, although there was a trend (G0=28%, G50=35% and G70=42%; p=0.377). Severity of nausea (measured by VAS 100 mm) was significantly increased with increasing N₂O concentration (G0=10.9, G50=12.7 and G70=20.5; p=0.027). The worst VAS score during 24 hours was used for the analysis. There was no difference in the use of a rescue antiemetic. Pain VAS scores and opioids consumption were not different among groups (at 2h and 24h after surgery).

**Conclusion:** N₂O increases the incidence of postoperative nausea after gynecologic
laparoscopic surgery. This preliminary findings indicate that N\textsubscript{2}O may increase PONV in dose dependent fashion. A study with sample size of > 400 patients in each group would be necessary to demonstrate a statistically significant difference among each of these three groups. We do not recommend using high concentration of N\textsubscript{2}O in this clinical setting.

Word Count: 342
**Introduction:**

Postoperative nausea and vomiting (PONV) are common complications after gynecologic laparoscopic surgery. In the absence of prophylactic antiemetics the incidence of PONV may be as high as 40% - 77% (1-4). The administration of prophylactic antiemetics, either alone or in combination have been shown to reduce this incidence. However, the routine administration of antiemetics increases costs and side effects (5,6). Reducing baseline risk has been recommended as an effective strategy for reducing PONV, including using specific anesthetic techniques that minimize the risk of PONV (7,8).

Nitrous oxide (N\textsubscript{2}O) has analgesic and sedative properties (9), but may potentially increase the incidence of PONV (10,11). N\textsubscript{2}O might increase incidence of PONV by several potential mechanisms: 1) increase in middle ear pressure (12,13); 2) bowel distension which is controversial (14-16). A recent meta-analysis revealed that each additional hour of anesthesia using N\textsubscript{2}O doubles the risk of bowel distension (odds ratio 2.09; 95% CI 1.27–3.59) compared with anesthesia using air/oxygen (14); 3) activation of the dopaminergic system in the chemoreceptor trigger zone (17); and 4) interaction with opioid receptors (18).

The evidence on PONV after N\textsubscript{2}O/volatile anesthetic (enflurane or isoflurane) in gynecologic laparoscopic surgery is controversial. N\textsubscript{2}O has been demonstrated to increase the incidence of PONV in some studies (10,11,19-22) but not others (23-26). Most of the studies on the influence of N\textsubscript{2}O on PONV used 60% to 70% inspiratory concentration (FI) of N\textsubscript{2}O. It is not clear if limiting N\textsubscript{2}O to a lower concentration decreases the risk of PONV. We postulate that inspiratory concentration of N\textsubscript{2}O has a dose/response relationship to the incidence of PONV. Our experimental hypothesis is that the incidence of PONV would increase as inspiratory N\textsubscript{2}O concentration increases from 50% and 70% when compared to air/oxygen (FI O\textsubscript{2} 30%) as a control group in gynecologic laparoscopic surgery under general anesthesia.
Methods:

After Institutional Review Board approval, written informed consent was obtained in 150 ASA PS I and II patients, between 19 to 75 years old, undergoing elective laparoscopic gynecological surgery (removal of the ovarian tumors and cysts, myomectomy, laparoscopic assisted vaginal hysterectomy and infertility surgery). The exclusion criteria were obesity (BMI >33 kg/m²), pregnancy, breast feeding, known hypersensitivity to drugs used in the study protocol, use of antiemetics, psychotropic drugs and steroids within 72 h before surgery. Patients with known comorbidities that may increase the incidence of PONV were also excluded, i.e. diseases which impaired gastric motility (diabetes mellitus, chronic cholecystitis, gastric and intestinal disease, neuromuscular disorders, neuropathies and liver dysfunction), vestibular disease, history of migraine headache, central nervous system injury, renal impairment, irregular menstrual cycle (duration of <21 or >35 days and/or variations between cycles >4 days), alcoholism and opioid addiction.

As per standard practice in the hospital, patients received 7.5 mg of midazolam PO 1 h before the surgery with no prophylactic antiemetics. Standard monitoring was applied including electrocardiography, noninvasive blood pressure, pulse oximetry and capnography.

After induction of anesthesia with thiopental 5 mg/kg and fentanyl 1-2 µg/kg, patients were manually ventilated via face mask with oxygen. Endotracheal intubation was facilitated with vecuronium 0.1 mg/kg IV. Patients were randomized by computer-generated random numbers to receive air and oxygen, FIO₂ 30% (group G0), 50% N₂O and oxygen (group G50) or 70% N₂O and oxygen (group G70). Anesthesia was maintained with sevoflurane (end tidal concentration ~1 minimum alveolar concentration [MAC]) and supplemental bolus doses of fentanyl IV (1 µg/kg) to keep heart rate and blood pressure within 20% of baseline values and additional vecuronium was administered to maintain a one or two twitches on the train-of-four
All patients received 10 ml/kg of crystalloids intraoperatively. Insertion of a nasogastric tube and gastric suction was not used. Neuromuscular blockade was antagonized with neostigmine 2.5 mg and atropine 1 mg IV.

Postoperatively, patients received 1000 ml (5 ml/kg/h) of crystalloids. The incidence of postoperative nausea, vomiting and the use of rescue antiemetic were collected at 2 and 24 hours after surgery. Severity of postoperative nausea and pain were evaluated using a 100 mm visual analogue scale (VAS) during the first 24 hours postoperatively (VAS 0 = no pain/nausea, 100 = maximal pain/nausea). A nausea VAS score was measured for each episode, but the worst score during the early and the late period was used for statistical evaluation. Patients who experienced at least one episode of nausea, vomiting or retching or any combination of these occurred during 24 hours postoperatively were considered to have had PONV. POV was defined as at least one episode of vomiting or retching that occurred within 24 hours postoperatively. PONV was defined as early (within first 2 hours) or late (2 to 24 hours postop). Clinical nurses specifically trained for the study collected the data and were blinded to the anesthesia technique used and randomization. Pain VAS score and total amount of opioids were recorded at 2 hours and at 24 hours postoperatively. Metoclopramide 10 mg IV was used as the rescue antiemetic. This was the standard clinical practice in the hospital. The administration of rescue antiemetic was based on the following criteria: patients who had two or more episodes of vomiting or retching within a period of 30 min, nausea lasting more than 15 min or nausea VAS score 50 mm or greater, or when a patient requested treatment. Diclofenac 75 mg IM was given immediately after surgery and if needed 12 hours later. For severe pain (VAS >40 mm) meperidine 25 mg up to 100 mg IV was used. All patients remained in the hospital for at least for 24 hours, as was our standard practice for laparoscopic gynecological surgery.

Statistical analysis
Calculation of sample size was based on preliminary data collected at General Hospital Zadar, Zadar, Croatia (27). A total of 45 patients per group would be sufficient to demonstrate a reduction of PONV by 20% from G70 to G50 and by 20% from G50 to G0 with a power of 0.8 and $\alpha < 0.05$. The expected incidence of PONV at 24 hours was for G0=30%, G50=50% and G70=70%. The data were analyzed using statistical program SAS 8.2. Quantitative values were compared using Kruskal-Wallis test and Mann-Whitney U test with correction for multiple comparisons between the groups. Categorical data were analyzed by Pearson Chi-Square test or Fisher's exact test with correction for multiple comparisons as appropriate. Data were expressed as number or percentages and mean±SD. A p value of < 0.05 was considered statistically significant.
Results:

One hundred thirty seven of 150 patients completed the study (G0=46, G50=46, G70=45). A total of 13 patients were excluded from the analysis. Four patients were excluded in G0: one patient was treated with corticosteroids for urticaria at induction of anesthesia, one patient had an anesthesia time less than 30 min, 2 patients had a protocol violation; 4 patients were excluded in G50: conversion to laparotomy, anesthesia time less than 30 min and 2 patients had a protocol violation; 5 patients were excluded in G70: 2 patients’ surgery was converted to laparotomy, 1 patient each had severe hypotension after induction which lasted more than 5 minutes, acute coronary syndrome postoperatively and anesthesia time less than 30 min.

There was no difference among groups regarding age, weight, height, BMI, ASA physical status, smoking status, history of motion sickness and/or PONV, phase of menstrual cycle, thiopental dose, duration of anesthesia and surgery and type of surgery (Table 1).

There was an overall difference in the incidence of PONV for 24 hours after surgery between the groups (p=0.018) (Table 2). G0 was significantly different vs G70 (p=0.018) but no difference was noted between G0 vs G50 (p=0.855) or G50 vs G70 (p=0.426) (Table 2). Although there was a trend towards an increase in the incidence of early PONV (two hours postoperatively) and late postoperative period (2-24h) with increasing N₂O concentration this did not reach statistical significance, p=0.071 and p=0.437, respectively (Table 2). The incidence of nausea showed a similar significant difference, with p=0.012, but the incidence of vomiting was no different between the groups, although there was a trend (Table 2). The severity of nausea was significantly increased with increasing N₂O concentration. There was no difference in the need for rescue antiemetic (Table 2), pain scores or opioids consumption between the groups (at 2h and 24h after surgery) (Table 3).
**Discussion:**

This study demonstrates that N\textsubscript{2}O when administered with oxygen and sevoflurane increases the incidence of postoperative nausea. The preliminary findings indicate that N\textsubscript{2}O may increase PONV in dose/respose fashion. The inspired concentration of 70\% N\textsubscript{2}O significantly increases the incidence of PONV at 24 hours, nausea at 24 hours and nausea VAS scores when compared with no N\textsubscript{2}O. In contrast, inspired concentration of 50\% N\textsubscript{2}O did not show significant increased PONV, nor nausea at 24 hours compared with patients who received only oxygen/air.

We chose 50\% and 70\% N\textsubscript{2}O in this study because of their clinical relevance. Inspired concentrations of N\textsubscript{2}O lower than 50\% are rarely used in anesthesia practice. The inspired concentration of 50\% N\textsubscript{2}O was chosen because it is generally perceived by anesthesiologists that this concentration has minimal effect in increasing the incidence of PONV (28). However, there is no data to support that assumption. 70\% N\textsubscript{2}O was selected as it represents the highest concentration of N\textsubscript{2}O used in clinical anesthesia practice.

All the reported studies on PONV after N\textsubscript{2}O/volatile anesthetic (enflurane or isoflurane) in gynecologic laparoscopic surgery compared a single inspired concentration of N\textsubscript{2}O, usually in the range of 66\%-70\%, with control (20,21,23,24). The results from this study agrees with Felts et al. who demonstrated that PONV is increased from 9.3\% in air/oxygen (FI O\textsubscript{2} 33\%) to 29.2\% with 66\% of N\textsubscript{2}O in oxygen following enflurane anesthesia for outpatient gynecologic laparoscopy (p<0.001) (21). Contrary to our study, Hovorka et al. did not find significant differences in the incidence of PONV among three groups of patients anesthetized with either isoflurane or enflurane with 70\% N\textsubscript{2}O in oxygen, and isoflurane without N\textsubscript{2}O, following gynecological laparoscopy (23). This discrepancy could be explained by the different duration of the anesthesia (the mean anesthesia times among groups were 37 to 40 minutes in Hovorka’s
study and 70 to 76 minutes in our study). One of the mechanisms of N₂O induced nausea and vomiting might be related to the middle ear pressure. The longer duration of N₂O exposure, as in our study, likely caused a larger increase in middle ear pressure as the time to reach peak middle ear pressure is about 60 min following the introduction of N₂O and about 30 minutes to return to baseline after N₂O is discontinued (12). Also, in Hovorka’s study smoking status was unknown which could bias the results.

Lonie et al. found significant increase only in the incidence of vomiting (from 17% without N₂O to 49% with N₂O 67% in oxygen following enflurane anesthesia), but not nausea between groups (20). This could be due to the more frequent administration of rescue antiemetic in our study. We treated the patients with severe nausea as well as patients who vomited (22% of patients in the both groups with N₂O and 15% in the group without N₂O). However, only a few patients were treated in Lonie’s study (7.5% patients in N₂O group and 7.1% in the group without N₂O). Sengupta et al. reported similar results as Lonie and colleagues, but the study was underpowered, with a smaller number of patients (total 64) and resulted in a non statistical difference between N₂O group and oxygen group, 33% vs 12.9%, respectively (24).

Recent results from the IMPACT study suggest that omitting N₂O in a multimodal PONV prophylaxis strategy further decrease the incidence of PONV by about 12%, if volatile anesthetic is used (29). However, the study did not address the dose response relationship of N₂O. The preliminary results from our study which showed that 70% N₂O increases the incidence of nausea concur with IMPACT study and a recent meta-analysis (10,29). Although our initial power analysis was expected to provide adequate power to demonstrate a dose response our actual results showed a smaller than expected difference. Assuming that this trend in the incidence of PONV at 24 hours were to persist, a study with sample size of 221 patients in each group would have been necessary to produce a statistically significant difference.
among each of three groups with a power of 0.8 and $\alpha < 0.05$. Using the same assumption it would require 410 patients per group to show the significant difference in the incidence of nausea at 24 hours, and 691 patients per group for the incidence of vomiting at 24 hours. The value of this study is that it provides preliminary data that indicate that N$_2$O may increase PONV in a dose/response fashion. We feel it would be valuable that a large prospective study should be performed to confirm if 50% N$_2$O has a lower incidence of PONV than 70% N$_2$O.

There are several limitations to our study. It can be criticized that we should have administered a prophylactic antiemetic or combination strategy given the high risk nature of this surgical population for PONV. We however wanted to specifically investigate the dose response effect of nitrous oxide which may have been masked by the use of prophylactic antiemetics. The difference in N$_2$O concentrations between the groups also means that the FI O$_2$ was different in G50 and G70. High FI O$_2$ (0.8) has been shown to reduce the incidence of PONV (30,31). However, more recent studies have cast doubt on previous findings. Purhonen et al. in an ambulatory gynecological laparoscopic patients showed that supplemental oxygen does not reduce the incidence of postoperative nausea and vomiting (32). The authors compared FI O$_2$ 30% and FI O$_2$ 80% oxygen with additional O$_2$ in PACU up to 1 hour but did not find difference in the PONV incidence after 24 hours, 62% vs 55%, respectively. Our study had only a 20% difference in FI O$_2$ among the groups compared with 50% difference in Purhonen’s study and we did not use supplemental oxygen in PACU. Therefore, the impact of oxygen in our study is likely to be small, if any. Furthermore, a recent large study involving 560 patients investigating the impact of oxygen on PONV concluded that oxygen has no impact of PONV irrespective of the site or surgery or the observational period (early or late PONV) (33).

In conclusion, we demonstrate that 70% N$_2$O increases the incidence of nausea and severity of nausea at 24 hours after laparoscopic gynecological surgery in the absence of any
prophylactic antiemetic. This preliminary findings indicate that N₂O may increase PONV in
dose dependent fashion. A study with sample size of > 400 patients in each group would be
necessary to produce a statistically significant difference among groups with no N₂O, 50% N₂O
and 70% N₂O. We do not recommend using high concentration of N₂O in this clinical setting.
